Introduction

This Programmer’s Guide is written for experienced programmers who know assembly language and are familiar with an assembler. The book does not teach the basics of assembly language; it does explain Microsoft-specific features. If you want to learn or review the basics of assembly language, refer to “Books for Further Reading” in this introduction.

This book teaches you how to write efficient code with the new and advanced features of MASM. Getting Started explains how to set up MASM 6.1. Environment and Tools introduces the integrated development environment called the Programmer’s WorkBench (PWB). It also includes a detailed reference to Microsoft tools and utilities such as Microsoft® CodeView®, LINK, and NMAKE. The Microsoft Macro Assembler Reference provides a full listing of all MASM instructions, directives, statements, and operators, and it serves as a quick reference to utility commands.

For more information on these same topics, see the online Microsoft Advisor, which is a complete reference to Macro Assembler language topics, to the utilities, and to PWB. You should be able to find most of the information you need in the Microsoft Advisor.

New and Extended Features in MASM 6.1

MASM 6.1 continues the break with tradition established by version 6.0. It incorporates conveniences of high-level languages while offering all the traditional advantages of assembly-language programming.

For example, MASM 6.1 includes the Programmer’s WorkBench, which provides the same integrated software development environment enjoyed by programmers of Microsoft high-level languages such as C and Basic. From within PWB you can edit, build, debug, or run a program. You can perform most of these operations with either menu selections or keyboard commands. You can also customize PWB to suit your individual programming and editing requirements and preferences.
MASM Features New Since Version 5.1

MASM 6.1 includes several features designed to make programming more efficient and productive. The following list briefly describes how MASM 6.1 improves on the language features of the popular version 5.1.

- MASM 6.1 has many enhancements related to types. You can now use the same type specifiers in initializations as in other contexts (BYTE instead of DB). You can also define your own types, including pointer types, with the new TYPEDEF directive. See Chapter 3, “Using Addresses and Pointers,” and Chapter 4, “Defining and Using Simple Data Types.”

- The syntax for defining and using structures and records has been enhanced since version 5.1. You can also define unions with the new UNION directive. See Chapter 5, “Defining and Using Complex Data Types.”

- MASM now generates complete CodeView information for all types. See Chapter 3, “Using Addresses and Pointers,” and Chapter 4, “Defining and Using Simple Data Types.”

- New control-flow directives let you use high-level-language constructs such as loops and if-then-else blocks defined with .REPEAT and .UNTIL (or .UNTILCXZ); .WHILE and .ENDD; and .IF, .ELSE, and .ELSEIF. The assembler generates the appropriate code to implement the control structure. See Chapter 7, “Controlling Program Flow.”

- MASM now has more powerful features for defining and calling procedures. The extended PROC syntax for generating stack frames has been enhanced since version 5.1. You can also use the PROTO directive to prototype a procedure, which you can then call with the INVOKE directive. INVOKE automatically generates code to pass arguments (converting them to a related type, if appropriate) and makes the call according to the specified calling convention. See Chapter 7, “Controlling Program Flow.”

- MASM optimizes jumps by automatically determining the most efficient coding for a jump and then generating the appropriate code. See Chapter 7, “Controlling Program Flow.”

- Maintaining multiple-module programs is easier in MASM 6.1 than in version 5.1. The EXTERNDEF and PROTO directives make it easy to maintain all global definitions in include files shared by all the source modules of a project. See Chapter 8, “Sharing Data and Procedures Among Modules and Libraries.”

The assembler has many new macro features that make complex macros clearer and easier to write:

- You can specify default values for macro arguments or mark arguments as required. And with the VARARG keyword, one parameter can accept a variable number of arguments.
You can implement loops inside of macros in various ways. For example, the new **WHILE** directive expands the statements in a macro body while an expression is not zero.

You can define macro functions, which return text macros. Several predefined text macros are also provided for processing strings. Macro operators and other features related to processing text macros and macro arguments have been enhanced. For more information on all these macro features, see Chapter 9, “Using Macros.”

MASM 6.1 has other improved capabilities, such as:

- The **.STARTUP** and **.EXIT** directives automatically generate appropriate startup and exit code for your assembly-language programs. See Chapter 2, “Organizing Segments.”
- MASM 6.1 supports flat memory model, available with the new Microsoft® Windows NT™ operating system. Flat model allows segments as large as 4 gigabytes instead of 64K (kilobytes). Offsets are 32 bits instead of 16 bits. See Chapter 2, “Organizing Segments.”
- The program H2INC.EXE converts C include files to MASM include files and translates data structures and declarations. See Chapter 20 in *Environment and Tools*.
- MASM 6.1 provides a library of assembly routines that let you create a terminate-and-stay-resident program (TSR) in a high-level language.

MASM 6.1 includes many other minor new features as well as extensive support for features of earlier versions of MASM. For a complete list of enhancements, refer to Appendix A, “Differences between MASM 6.1 and 5.1.” The cross-references in Appendix A guide you to the chapters where the new features are described in detail.

**MASM Features New Since Version 6.0**

MASM 6.1 offers several new features:

- **ML** now runs in 32-bit protected mode under MS-DOS, giving it direct access to extended memory for assembling very large source files.
- A collection of tools lets you write a dynamic-link library (DLL) for the Microsoft® Windows™ operating system without the Windows Software Development Kit. The LIBW.LIB library provides access to all functions in the Windows application programming interface (API), so your DLL can display menus, dialog boxes, and scroll bars. Chapter 10, “Writing a Dynamic-Link Library for Windows,” shows you how.
Program listings now show instruction timings. The number of required processor cycles appears adjacent to each instruction in the listing, based on the selected processor. For an example listing and instructions on how to use this feature, see Appendix C, “Generating and Reading Assembly Listings.”

All utilities have been updated for version 6.1. Documentation is clearer and better arranged, with a new Environment and Tools reference book.

Version 6.1 generates debugging information for CodeView version 4.0 and later.

MASM 6.1 provides even greater compatibility with version 5.1 than does MASM 6.0. Many programs written with version 5.1 will assemble unchanged under MASM 6.1.

ML and MASM Command Lines

MASM 6.1 provides an updated version of the command-line driver, ML, introduced in version 6.0. ML is more powerful and flexible than the MASM driver of version 5.1. ML assembles and links with one command. It recognizes all the old MASM driver command syntax, however, to support existing batch files and makefiles that use MASM command lines.

Note The name MASM has traditionally referred to the Microsoft Macro Assembler. It is used in that context throughout this book. However, MASM also refers to MASM.EXE, which has been replaced by ML.EXE. In MASM 6.1, MASM.EXE is a small utility that translates command-line options to those accepted by ML.EXE, and then calls ML.EXE. The distinction between ML.EXE and MASM.EXE is made whenever necessary. Otherwise, MASM refers to the assembler and its features.

Compatibility with Earlier Versions of MASM

MASM 6.1 is fully compatible with version 6.0 and, in many cases, with version 5.1. Code written for MASM 5.1 will often assemble correctly without modification under MASM 6.1. However, MASM 6.1 provides the OPTION directive to let you selectively modify the assembly process. In particular, you can use the M510 argument with OPTION or the /Zm command-line option to set most features to be compatible with version 5.1 code.

For information about obsolete features that will not assemble correctly under MASM 6.1, see Appendix A, “Differences Between MASM 6.1 and 5.1.” The appendix also explains how to update code to use the new features.
A Word About Instruction Timings

As an assembly-language programmer, whether novice or expert, you are probably interested in producing lightning-fast code. After all, one of the main reasons to program in assembly is to take advantage of its ability to streamline execution speeds to the limit of the processor. This book will help you write efficient and fast programs.

When discussing the speed of individual instructions, the chapters in this book often speak of “timing,” which is the number of processor cycles required to carry out an instruction. The Reference lists instruction timings for processors in the 8086 family. It is tempting to use timing as the only criterion when judging an instruction’s actual execution speed, but the world within the processor is not so simple.

The clock for instruction timing does not begin ticking until the processor has read and begins to execute an instruction. When you read about instruction timings (in this book or any other), keep in mind that other factors also influence the real speed of an instruction: the instruction’s size, whether it resides in cache memory, whether it accesses memory, its position in the processor’s prefetch queue, and the processor type. These factors make it impossible to say precisely how fast an instruction executes. Accept the references to timing in this book as guidelines, but use these simple rules to write fast code:

- Whenever possible, use registers rather than constant values, and constant values rather than memory.
- Minimize changes in program flow.
- Smaller is often better. For example, the instructions

```
    dec bx
    sub bx, 1
```

accomplish the same thing and have the same timings on 80386/486 processors. But the first instruction is 3 bytes smaller than the second, and so may reach the processor faster.

- When possible, use the string instructions described in Chapter 5, “Defining and Using Complex Data Types.”
Books for Further Reading

The following books may help you to learn to program in assembly language or write specialized programs. These books are listed only for your convenience. Microsoft makes no specific recommendations concerning any of these books.

Books About Programming in Assembly Language

Books About MS-DOS and BIOS

Books and Articles About Windows

Books About Other Topics

Document Conventions
The following document conventions are used throughout this manual:

<table>
<thead>
<tr>
<th>Example of Convention</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SAMPLE2.ASM</td>
<td>Uppercase letters indicate filenames, segment names, registers, and terms used at the command level.</td>
</tr>
<tr>
<td>.MODEL</td>
<td>Boldface type indicates assembly-language directives, instructions, type specifiers, and predefined macros, as well as keywords in other programming languages.</td>
</tr>
<tr>
<td><em>placeholder</em></td>
<td>Italic letters indicate placeholders for information you must supply, such as a filename. Italics are used occasionally for emphasis in the text.</td>
</tr>
<tr>
<td>tar get</td>
<td>This font is used to indicate example programs, user input, and screen output.</td>
</tr>
<tr>
<td>;</td>
<td>A semicolon in the first column of an example signals illegal code. A semicolon also marks a comment.</td>
</tr>
</tbody>
</table>
SHIFT  
Small capital letters signify names of keys on the keyboard. Notice that a plus (+) indicates a combination of keys. For example, CTRL+E means to hold down the CTRL key while pressing the E key.

[argument]  
Items inside double square brackets are optional.

{register|memory}  
Braces and a vertical bar indicate a choice between two or more items. You must choose one of the items unless double square brackets surround the braces.

Repeating elements...  
A horizontal ellipsis (...) following an item indicates that more items having the same form may appear.

Program  
A vertical ellipsis tells you that part of a program has been intentionally omitted.

Fragment

Getting Assistance and Reporting Problems

If you need help or think you have discovered a problem in the software, please provide the following information to help us locate the source of the problem:

- The version of MS-DOS or Windows you run.
- Your system configuration: the type of machine you use, its total memory, and its total free memory at assembler execution time, as well as any other information you think might be useful.
- The command line you used for the assembler, linker, or other MASM tool that was running when the problem occurred.
- Any object files or libraries you linked with if the problem occurred at link time.

If your program is very large, reduce it to the smallest possible program that still produces the problem.

Note the circumstances of the error and notify Microsoft Corporation by following the instructions in the section “Microsoft Support Services” in the introduction to Environment and Tools. If you have comments or suggestions regarding any of the books accompanying this product, please indicate them on the Document Feedback page at the back of this book and send it to Microsoft.

If you have not yet registered your copy of the Macro Assembler, you should fill out and return the Registration Card. This enables Microsoft to keep you informed of updates and other information about the assembler.
CHAPTER 1

Understanding Global Concepts

With the development of the Microsoft Macro Assembler (MASM) version 6.1, you now have more options available to you for approaching a programming task. This chapter explains the general concepts of programming in assembly language, beginning with the environment and a review of the components you need to work in the assembler environment. Even if you are familiar with previous versions of MASM, you should examine this chapter for information on new terms and features.

The first section of this chapter reviews available processors and operating systems and how they work together. The section also discusses segmented architecture and how it affects a protected-mode operating environment such as Windows.

The second section describes some of the language components of MASM that are common to most programs, such as reserved words, constant expressions, operators, and registers. The remainder of this book was written with the assumption that you understand the information presented in this section.

The last section summarizes the assembly process, from assembling a program through running it. You can affect this process by the way you develop your code. Finally, this section explores how you can change the assembly process with the OPTION directive and conditional assembly.

The Processing Environment

The processing environment for MASM 6.1 includes the processor on which your programs run, the operating system your programs use, and the aspects of the segmented architecture that influence the choice of programming models. This section summarizes these elements of the environment and how they affect your programming choices.
8086-Based Processors

The 8086 “family” of processors uses segments to control data and code. The later 8086-based processors have larger instruction sets and more memory capacity, but they still support the same segmented architecture. Knowing the differences between the various 8086-based processors can help you select the appropriate target processor for your programs.

The instruction set of the 8086 processor is upwardly compatible with its successors. To write code that runs on the widest number of machines, select the 8086 instruction set. By using the instruction set of a more advanced processor, you increase the capabilities and efficiency of your program, but you also reduce the number of systems on which the program can run.

Table 1.1 lists modes, memory, and segment size of processors on which your application may need to run. Each processor is discussed in more detail following.

<table>
<thead>

Processor Modes

Real mode allows only one process to run at a time. The mode gets its name from the fact that addresses in real mode always correspond to real locations in memory. The MS-DOS operating system runs in real mode.

Windows 3.1 operates only in protected mode, but runs MS-DOS programs in real mode or in a simulation of real mode called virtual-86 mode. In protected mode, more than one process can be active at any one time. The operating system protects memory belonging to one process from access by another process; hence the name protected mode.

Protected-mode addresses do not correspond directly to physical memory. Under protected-mode operating systems, the processor allocates and manages memory dynamically. Additional privileged instructions initialize protected mode and control multiple processes. For more information, see “Operating Systems,” following.
8086 and 8088
The 8086 is faster than the 8088 because of its 16-bit data bus; the 8088 has only an 8-bit data bus. The 16-bit data bus allows you to use EVEN and ALIGN on an 8086 processor to word-align data and thus improve data-handling efficiency. Memory addresses on the 8086 and 8088 refer to actual physical addresses.

80186 and 80188
These two processors are identical to the 8086 and 8088 except that new instructions have been added and several old instructions have been optimized. These processors run significantly faster than the 8086.

80286
The 80286 processor adds some instructions to control protected mode, and it runs faster. It also provides protected mode services, allowing the operating system to run multiple processes at the same time. The 80286 is the minimum for running Windows 3.1 and 16-bit versions of OS/2®.

80386
Unlike its predecessors, the 80386 processor can handle both 16-bit and 32-bit data. It supports the entire instruction set of the 80286, and adds several new instructions as well. Software written for the 80286 runs unchanged on the 80386, but is faster because the chip operates at higher speeds.

The 80386 implements many new hardware-level features, including paged memory, multiple virtual 8086 processes, addressing of up to 4 gigabytes of memory, and specialized debugging registers. Thirty-two-bit operating systems such as Windows NT and OS/2 2.0 can run only on an 80386 or higher processor.

80486
The 80486 processor is an enhanced version of the 80386, with instruction “pipelining” that executes many instructions two to three times faster. The chip incorporates both a math coprocessor and an 8K (kilobyte) memory cache. (The math coprocessor is disabled on a variation of the chip called the 80486SX.) The 80486 includes new instructions and is fully compatible with 80386 software.

8087, 80287, and 80387
These math coprocessors work concurrently with the 8086 family of processors. Performing floating-point calculations with math coprocessors is up to 100 times faster than emulating the calculations with integer instructions. Although there are technical and performance differences among the three coprocessors, the main difference to the applications programmer is that the 80287 and 80387 can
operate in protected mode. The 80387 also has several new instructions. The 80486 does not use any of these coprocessors; its floating-point processor is built in and is functionally equivalent to the 80387.

Operating Systems

With MASM, you can create programs that run under MS-DOS, Windows, or Windows NT—or all three, in some cases. For example, ML.EXE can produce executable files that run in any of the target environments, regardless of the programmer’s environment. For information on building programs for different environments, see “Building and Running Programs” in Help for PWB.

MS-DOS and Windows 3.1 provide different processing modes. MS-DOS runs in the single-process real mode. Windows 3.1 operates in protected mode, allowing multiple processes to run simultaneously.

Although Windows requires another operating system for loading and file services, it provides many functions normally associated with an operating system. When an application requests an MS-DOS service, Windows often provides the service without invoking MS-DOS. For consistency, this book refers to Windows as an operating system.

MS-DOS and Windows (in protected mode) differ primarily in system access methods, size of addressable memory, and segment selection. Table 1.2 summarizes these differences.

<table>

</tbody>
</table>

MS-DOS

In real-mode programming, you can access system functions by calling MS-DOS, calling the basic input/output system (BIOS), or directly addressing hardware. Access is through MS-DOS Interrupt 21h.
Windows
As you can see in Table 1.2, protected mode allows for much larger data structures than real mode, since addressable memory extends to 16 megabytes. In protected mode, segment registers contain selector values rather than actual segment addresses. These selectors cannot be calculated by the program; they must be obtained by calling the operating system. Programs that attempt to calculate segment values or to address memory directly do not work in protected mode.

Protected mode uses privilege levels to maintain system integrity and security. Programs cannot access data or code that is in a higher privilege level. Some instructions that directly access ports or affect interrupts (such as CLI, STI, IN, and OUT) are available at privilege levels normally used only by systems programmers.

Windows protected mode provides each application with up to 16 megabytes of “virtual memory,” even on computers that have less physical memory. The term virtual memory refers to the operating system’s ability to use a swap area on the hard disk as an extension of real memory. When a Windows application requires more memory than is available, Windows writes sections of occupied memory to the swap area, thus freeing those sections for other use. It then provides the memory to the application that made the memory request. When the owner of the swapped data regains control, Windows restores the data from disk to memory, swapping out other memory if required.

Windows NT
Windows NT uses the so-called “flat model” of 80386/486 processors. This model places the processor’s entire address space within one 32-bit segment. The section “Defining Basic Attributes with .MODEL” in Chapter 2 explains how to use the flat model. In flat model, your program can (in theory) access up to 4 gigabytes of virtual memory. Since code, data, and stack reside in the same segment, each segment register can hold the same value, which need never change.

Segmented Architecture
The 8086 family of processors employs a segmented architecture—that is, each address is represented as a segment and an offset. Segmented addresses affect many aspects of assembly-language programming, especially addresses and pointers.

Segmented architecture was originally designed to enable a 16-bit processor to access an address space larger than 64K. (The section “Segmented Addressing,” later in this chapter, explains how the processor uses both the segment and offset to create addresses larger than 64K.) MS-DOS is an example of an operating system that uses segmented architecture on a 16-bit processor.
With the advent of protected-mode processors such as the 80286, segmented architecture gained a second purpose. Segments can separate different blocks of code and data to protect them from undesirable interactions. Windows takes advantage of the protection features of the 16-bit segments on the 80286.

Segmented architecture went through another significant change with the release of 32-bit processors, starting with the 80386. These processors are compatible with the older 16-bit processors, but allow flat model 32-bit offset values up to 4 gigabytes. Offset values of this magnitude remove the memory limitations of segmented architecture. The Windows NT operating system uses 32-bit addressing.

Segment Protection

Segmented architecture is an important part of the Windows memory-protection scheme. In a “multitasking” operating system in which numerous programs can run simultaneously, programs cannot access the code and data of another process without permission.

In MS-DOS, the data and code segments are usually allocated adjacent to each other, as shown in Figure 1.1. In Windows, the data and code segments can be anywhere in memory. The programmer knows nothing about, and has no control over, their location. The operating system can even move the segments to a new memory location or to disk while the program is running.

Segment protection makes software development easier and more reliable in Windows than in MS-DOS, because Windows immediately detects illegal
memory accesses. The operating system intercepts illegal memory accesses, terminates the program, and displays a message. This makes it easier for you to track down and fix the bug.

Because it runs in real mode, MS-DOS contains no mechanism for detecting an improper memory access. A program that overwrites data not belonging to it may continue to run and even terminate correctly. The error may not surface until later, when MS-DOS or another program reads the corrupted memory.

**Segmented Addressing**

Segmented addressing refers to the internal mechanism that combines a segment value and an offset value to form a complete memory address. The two parts of an address are represented as

```
segment:offset
```

The *segment* portion always consists of a 16-bit value. The *offset* portion is a 16-bit value in 16-bit mode or a 32-bit value in 32-bit mode.

In real mode, the segment value is a physical address that has an arithmetic relationship to the offset value. The segment and offset together create a 20-bit physical address (explained in the next section). Although 20-bit addresses can access up to 1 megabyte of memory, the BIOS and operating system on International Standard Architecture (IBM PC/AT and compatible) computers use part of this memory, leaving the remainder available for programs.

**Segment Arithmetic**

Manipulating segment and offset addresses directly in real-mode programming is called “segment arithmetic.” Programs that perform segment arithmetic are not portable to protected-mode operating systems, in which addresses do not correspond to a known segment and offset.

To perform segment arithmetic successfully, it helps to understand how the processor combines a 16-bit segment and a 16-bit offset to form a 20-bit linear address. In effect, the segment selects a 64K region of memory, and the offset selects the byte within that region. Here’s how it works:

1. The processor shifts the segment address to the left by four binary places, producing a 20-bit address ending in four zeros. This operation has the effect of multiplying the segment address by 16.
2. The processor adds this 20-bit segment address to the 16-bit offset address. The offset address is not shifted.
3. The processor uses the resulting 20-bit address, called the “physical address,” to access an actual location in the 1-megabyte address space.
Figure 1.2 illustrates this process.

Figure 1.2  Calculating Physical Addresses

A 20-bit physical address may actually be specified by 4,096 equivalent segment:offset addresses. For example, the addresses 0000:F800, 0F00:0800, and 0F80:0000 all refer to the same physical address 0F800.

Language Components of MASM

Programming with MASM requires that you understand the MASM concepts of reserved words, identifiers, predefined symbols, constants, expressions, operators, data types, registers, and statements. This section defines important terms and provides lists that summarize these topics. For detailed information, see Help or the Reference.

Reserved Words

A reserved word has a special meaning fixed by the language. You can use it only under certain conditions. Reserved words in MASM include:

- Instructions, which correspond to operations the processor can execute.
- Directives, which give commands to the assembler.
- Attributes, which provide a value for a field, such as segment alignment.
- Operators, which are used in expressions.
Predefined symbols, which return information to your program.

MASM reserved words are not case sensitive except for predefined symbols (see “Predefined Symbols,” later in this chapter).

The assembler generates an error if you use a reserved word as a variable, code label, or other identifier within your source code. However, if you need to use a reserved word for another purpose, the **OPTION NOKEYWORD** directive can selectively disable a word’s status as a reserved word.

For example, to remove the **STR** instruction, the **MASK** operator, and the **NAME** directive from the set of words MASM recognizes as reserved, use this statement in the code segment of your program before the first reference to **STR**, **MASK**, or **NAME**:

```
OPTION NOKEYWORD: <STR MASK NAME>
```

The section “Using the OPTION Directive,” later in this chapter, discusses the **OPTION** directive. Appendix D provides a complete list of MASM reserved words.

With the /Zm command-line option or **OPTION M510** in effect, MASM does not reserve any operators or instructions that do not apply to the current CPU mode. For example, you can use the symbol **ENTER** when assembling under the default CPU mode but not under .286 mode, since the 80186/486 processors recognize **ENTER** as an instruction. The **USE32**, **FLAT**, **FAR32**, and **NEAR32** segment types and the 80386/486 register names are not keywords with processors other than the 80386/486.

**Identifiers**

An identifier is a name that you invent and attach to a definition. Identifiers can be symbols representing variables, constants, procedure names, code labels, segment names, and user-defined data types such as structures, unions, records, and types defined with **TYPEDEF**. Identifiers longer than 247 characters generate an error.

Certain restrictions limit the names you can use for identifiers. Follow these rules to define a name for an identifier:

- The first character of the identifier can be an alphabetic character (A–Z) or any of these four characters: @ _ $ ?
- The other characters in the identifier can be any of the characters listed above or a decimal digit (0–9).

Avoid starting an identifier with the at sign (@), because MASM 6.1 predefines some special symbols starting with @ (see “Predefined Symbols,” following).
Beginning an identifier with @ may also cause conflicts with future versions of the Macro Assembler.

The symbol—and thus the identifier—is visible as long as it remains within scope. (For more information about visibility and scope, see “Sharing Symbols with Include Files” in Chapter 8.)

Predefined Symbols

The assembler includes a number of predefined symbols (also called predefined equates). You can use these symbol names at any point in your code to represent the equate value. For example, the predefined equate @FileName represents the base name of the current file. If the current source file is TASK.ASM, the value of @FileName is TASK. The MASM predefined symbols are listed according to the kinds of information they provide. Case is important only if the /Cp option is used. (For additional details, see Help on ML command-line options.)

The predefined symbols for segment information include:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>@code</td>
<td>Returns the name of the code segment.</td>
</tr>
<tr>
<td>@CodeSize</td>
<td>Returns an integer representing the default code distance.</td>
</tr>
<tr>
<td>@CurSeg</td>
<td>Returns the name of the current segment.</td>
</tr>
<tr>
<td>@data</td>
<td>Expands to DGROUP.</td>
</tr>
<tr>
<td>@DataSize</td>
<td>Returns an integer representing the default data distance.</td>
</tr>
<tr>
<td>@fardata</td>
<td>Returns the name of the segment defined by the .FARDATA directive.</td>
</tr>
<tr>
<td>@fardata?</td>
<td>Returns the name of the segment defined by the .FARDATA? directive.</td>
</tr>
<tr>
<td>@Model</td>
<td>Returns the selected memory model.</td>
</tr>
<tr>
<td>@stack</td>
<td>Expands to DGROUP for near stacks or STACK for far stacks. (See “Creating a Stack” in Chapter 2.)</td>
</tr>
<tr>
<td>@WordSize</td>
<td>Provides the size attribute of the current segment.</td>
</tr>
</tbody>
</table>

The predefined symbols for environment information include:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>@Cpu</td>
<td>Contains a bit mask specifying the processor mode.</td>
</tr>
<tr>
<td>@Environ</td>
<td>Returns values of environment variables during assembly.</td>
</tr>
<tr>
<td>@Interface</td>
<td>Contains information about the language parameters.</td>
</tr>
<tr>
<td>@Version</td>
<td>Represents the text equivalent of the MASM version number. In MASM 6.1, this expands to 610.</td>
</tr>
</tbody>
</table>
The predefined symbols for date and time information include:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>@Date</td>
<td>Supplies the current system date during assembly.</td>
</tr>
<tr>
<td>@Time</td>
<td>Supplies the current system time during assembly.</td>
</tr>
</tbody>
</table>

The predefined symbols for file information include:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>@FileCur</td>
<td>Names the current file (base and suffix).</td>
</tr>
<tr>
<td>@FileName</td>
<td>Names the base name of the main file being assembled as it appears on the command line.</td>
</tr>
<tr>
<td>@Line</td>
<td>Gives the source line number in the current file.</td>
</tr>
</tbody>
</table>

The predefined symbols for macro string manipulation include:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>@CatStr</td>
<td>Returns concatenation of two strings.</td>
</tr>
<tr>
<td>@InStr</td>
<td>Returns the starting position of a string within another string.</td>
</tr>
<tr>
<td>@SizeStr</td>
<td>Returns the length of a given string.</td>
</tr>
<tr>
<td>@SubStr</td>
<td>Returns substring from a given string.</td>
</tr>
</tbody>
</table>

**Integer Constants and Constant Expressions**

An integer constant is a series of one or more numerals followed by an optional radix specifier. For example, in these statements

\[
\begin{align*}
   & \text{mov} \ ax, 25 \\
   & \text{mov} \ bx, 0B3h
\end{align*}
\]

the numbers 25 and 0B3h are integer constants. The h appended to 0B3 is a radix specifier. The specifiers are:

- y for binary (or b if the default radix is not hexadecimal)
- o or q for octal
- t for decimal (or d if the default radix is not hexadecimal)
- h for hexadecimal

Radix specifiers can be either uppercase or lowercase letters; sample code in this book is in lowercase. If you do not specify a radix, the assembler interprets the integer according to the current radix. The default radix is decimal, but you can change the default with the .RADIX directive.
Hexadecimal numbers must always start with a decimal digit (0–9). If necessary, add a leading zero to distinguish between symbols and hexadecimal numbers that start with a letter. For example, MASM interprets \texttt{ABCh} as an identifier. The hexadecimal digits A through F can be either uppercase or lowercase letters. Sample code in this book is in uppercase letters.

Constant expressions contain integer constants and (optionally) operators such as shift, logical, and arithmetic operators. The assembler evaluates constant expressions at assembly time. (In addition to constants, expressions can contain labels, types, registers, and their attributes.) Constant expressions do not change value during program execution.

**Symbolic Integer Constants**
You can define symbolic integer constants with either of the data assignment directives, \texttt{EQU} or the equal sign (=). These directives assign values to symbols during assembly, not during program execution. Symbolic constants are used to assign names to constant values. You can use a symbol with an assigned value in place of an immediate operand. For example, instead of referring in your code to keyboard scan codes with numbers such as 30 or 48, you can create more recognizable symbols:

\begin{verbatim}
SCAN_A EQU 30
SCAN_B EQU 48
\end{verbatim}

then use the appropriate symbol in your program rather than the number. Using symbolic constants instead of undescrptive numbers makes your code more readable and easier to maintain. The assembler does not allocate data storage when you use either \texttt{EQU} or =. It simply replaces each occurrence of the symbol with the value of the expression.

The directives \texttt{EQU} and = have slightly different purposes. Integers defined with the = directive can be redefined with another value in your source code, but those defined with \texttt{EQU} cannot. Once you’ve defined a symbolic constant with the \texttt{EQU} directive, attempting to redefine it generates an error. The syntax is:

\begin{verbatim}
symbol EQU expression
\end{verbatim}

The \texttt{symbol} is a unique name of your choice, except for words reserved by MASM. The \texttt{expression} can be an integer, a constant expression, a one- or two-character string constant (four-character on the 80386/486), or an expression that evaluates to an address. Symbolic constants let you change a constant value used throughout your source code by merely altering \texttt{expression} in the definition. This removes the potential for error and saves you the inconvenience of having to find and replace each occurrence of the constant in your program.
The following example shows the correct use of **EQU** to define symbolic integers.

\[
\begin{align*}
\text{column} & \quad \text{EQU} \quad 80 \quad ; \quad \text{Constant} \quad - \quad 80 \\
\text{row} & \quad \text{EQU} \quad 25 \quad ; \quad \text{Constant} \quad - \quad 25 \\
\text{screen} & \quad \text{EQU} \quad \text{column} \times \text{row} \\ & \quad ; \quad \text{Constant} \quad - \quad 2000 \\
\text{line} & \quad \text{EQU} \quad \text{row} \\ & \quad ; \quad \text{Constant} \quad - \quad 25
\end{align*}
\]

```assembly
.data
.text
.nop
.nop

mov cx, column
mov bx, line
```

The value of a symbol defined with the **=** directive can be different at different places in the source code. However, a constant value is assigned during assembly for each use, and that value does not change at run time.

The syntax for the **=** directive is:

\[
symbol = expression
\]

### Size of Constants

The default word size for MASM 6.1 expressions is 32 bits. This behavior can be modified using **OPTION EXPR16** or **OPTION M510**. Both of these options set the expression word size to 16 bits, but **OPTION M510** affects other assembler behavior as well (see Appendix A).

It is illegal to change the expression word size once it has been set with **OPTION M510**, **OPTION EXPR16**, or **OPTION EXPR32**. However, you can repeat the same directive in your source code as often as you wish. You can place the same directive in every include file, for example.

### Operators

Operators are used in expressions. The value of the expression is determined at assembly time and does not change when the program runs.

Operators should not be confused with processor instructions. The reserved word **ADD** is an instruction; the plus sign (+) is an operator. For example, \texttt{Amount +2} illustrates a valid use of the plus operator (+). It tells the assembler to add 2 to the constant value \texttt{Amount}, which might be a value or an address. Contrast this operation, which occurs at assembly time, with the processor’s **ADD** instruction. **ADD** tells the processor at run time to add two numbers and store the result.
The assembler evaluates expressions that contain more than one operator according to the following rules:

- Operations in parentheses are performed before adjacent operations.
- Binary operations of highest precedence are performed first.
- Operations of equal precedence are performed from left to right.
- Unary operations of equal precedence are performed right to left.

Table 1.3 lists the order of precedence for all operators. Operators on the same line have equal precedence.

**Table 1.3 Operator Precedence**

<table>
<thead>
<tr>

</tbody>
</table>

### Data Types

A “data type” describes a set of values. A variable of a given type can have any of a set of values within the range specified for that type.

The intrinsic types for MASM 6.1 are **BYTE, SBYTE, WORD, SWORD, DWORD, SDWORD, FWORD, QWORD**, and **TBYTE**. These types define integers and binary coded decimals (BCDs), as discussed in Chapter 6. The signed data types **SBYTE, SWORD, and SDWORD** work in conjunction with directives such as **INVOKE** (for calling procedures) and **.IF** (introduced in Chapter 7). The **REAL4, REAL8, and REAL10** directives define floating-point types. (See Chapter 6.)
Versions of MASM prior to 6.0 had separate directives for types and initializers. For example, **BYTE** is a type and **DB** is the corresponding initializer. The distinction does not apply in MASM 6.1. You can use any type (intrinsic or user-defined) as an initializer.

MASM does not have specific types for arrays and strings. However, you can treat a sequence of data units as arrays, and character or byte sequences as strings. (See “Arrays and Strings” in Chapter 5.)

Types can also have attributes such as **langtype** and **distance** (**NEAR** and **FAR**). For information on these attributes, see “Declaring Parameters with the PROC Directive” in Chapter 7.

You can also define your own types with **STRUCT**, **UNION**, and **RECORD**. The types have fields that contain string or numeric data, or records that contain bits. These data types are similar to the user-defined data types in high-level languages such as C, Pascal, and FORTRAN. (See Chapter 5, “Defining and Using Complex Data Types.”)

You can define new types, including pointer types, with the **TYPEDEF** directive. **TYPEDEF** assigns a **qualifiedtype** (explained in the following) to a **typename** of your choice. This lets you build new types with descriptive names of your choosing, making your programs more readable. For example, the following statement makes the symbol **CHAR** a synonym for the intrinsic type **BYTE**:

```
CHAR    TYPEDEF BYTE
```

The **qualifiedtype** is any type or pointer to a type of the form:

```
[[distance]] PTR [[qualifiedtype]]
```

where **distance** is **NEAR**, **FAR**, or any distance modifier. (For more information on **distance**, see “Declaring Parameters with the PROC Directive” in Chapter 7.)

The **qualifiedtype** can also be any type previously defined with **TYPEDEF**. For example, if you use **TYPEDEF** to create an alias for **BYTE**—say, **CHAR** as in the preceding example—you can use **CHAR** as a **qualifiedtype** when defining the pointer type **PCHAR**, like this:

```
CHAR    TYPEDEF BYTE
PCHAR    TYPEDEF PTR CHAR
```

The typename **CHAR** in the first line becomes a **qualifiedtype** in the second line. Use of the **TYPEDEF** directive to define pointers is explained in “Accessing Data with Pointers and Addresses” in Chapter 3.
Since distance and qualifiedtype are optional syntax elements, you can use variables of type PTR or FAR PTR. You can also define procedure prototypes with qualifiedtype. For more information about procedure prototypes, see “Declaring Procedure Prototypes” in Chapter 7.

These rules govern the use of qualifiedtype:

- The only component of a qualifiedtype definition that can be forward-referenced is a structure or union type identifier.
- If you do not specify distance, the assembler assumes a distance that corresponds to the memory model. The assumed distance is NEAR for tiny, small, and medium models, and FAR for other models.
- If you do not specify a memory model with .MODEL, the assembler assumes SMALL model (and therefore NEAR pointers).

You can use a qualifiedtype in seven places:

<table>
<thead>
<tr>
<th>Use</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>In procedure arguments</td>
<td>proc1 PROC pMsg:PTR BYTE</td>
</tr>
<tr>
<td>In prototype arguments</td>
<td>proc2 PROTO pMsg:FAR PTR WORD</td>
</tr>
<tr>
<td>With local variables declared inside</td>
<td>LOCAL pMsg:PTR</td>
</tr>
<tr>
<td>procedures</td>
<td></td>
</tr>
<tr>
<td>With the LABEL directive</td>
<td>TempMsg LABEL PTR WORD</td>
</tr>
<tr>
<td>With the EXTERN and EXTERNDEF directives</td>
<td>EXTERN pMsg: FAR PTR BYTE</td>
</tr>
<tr>
<td></td>
<td>EXTERNDEF MyProc:PROTO</td>
</tr>
<tr>
<td>With the COMM directive</td>
<td>COMM var1:WORD 3</td>
</tr>
<tr>
<td>With the TYPEDEF directive</td>
<td>PBYTE TYPEDEF PTR BYTE</td>
</tr>
<tr>
<td></td>
<td>PFUNC TYPEDEF PROTO MyProc</td>
</tr>
</tbody>
</table>

“Defining Pointer Types with TYPEDEF” in Chapter 3 shows ways to write a TYPEDEF type for a qualifiedtype. Attributes such as NEAR and FAR can also apply to a qualifiedtype.

You can determine an accurate definition for TYPEDEF and qualifiedtype from the BNF grammar definitions given in Appendix B. The BNF grammar defines each component of the syntax for any directive, showing the recursive properties of components such as qualifiedtype.

Registers

The 8086 family of processors have the same base set of 16-bit registers. Each processor can treat certain registers as two separate 8-bit registers. The 80386/486 processors have extended 32-bit registers. To maintain compatibility
with their predecessors, 80386/486 processors can access their registers as 16-bit or, where appropriate, as 8-bit values.

Figure 1.3 shows the registers common to all the 8086-based processors. Each register has its own special uses and limitations.

Figure 1.3 Registers for 8088–80286 Processors

80386/486 Only

The 80386/486 processors use the same 8-bit and 16-bit registers used by the rest of the 8086 family. All of these registers can be further extended to 32 bits, except segment registers, which always occupy 16 bits. The extended register names begin with the letter “E.” For example, the 32-bit extension of AX is EAX. The 80386/486 processors have two additional segment registers, FS and GS. Figure 1.4 shows the extended registers of the 80386/486.
### Segment Registers

At run time, all addresses are relative to one of four segment registers: CS, DS, SS, or ES. (The 80386/486 processors add two more: FS and GS.) These registers, their segments, and their purposes include:

<table>
<thead>
<tr>
<th>Register and Segment</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>CS (Code Segment)</td>
<td>Contains processor instructions and their immediate operands.</td>
</tr>
<tr>
<td>DS (Data Segment)</td>
<td>Normally contains data allocated by the program.</td>
</tr>
<tr>
<td>SS (Stack Segment)</td>
<td>Contains the program stack for use by <strong>PUSH, POP, CALL,</strong> and <strong>RET</strong>.</td>
</tr>
</tbody>
</table>
Register and Segment | Purpose
---|---
ES (Extra Segment) | References secondary data segment. Used by string instructions.
FS, GS | Provides extra segments on the 80386/486.

**General-Purpose Registers**
The AX, DX, CX, BX, BP, DI, and SI registers are 16-bit general-purpose registers, used for temporary data storage. Since the processor accesses registers more quickly than it accesses memory, you can make your programs run faster by keeping the most-frequently used data in registers.

The 8086-based processors do not perform memory-to-memory operations. For example, the processor cannot directly copy a variable from one location in memory to another. You must first copy from memory to a register, then from the register to the new memory location. Similarly, to add two variables in memory, you must first copy one variable to a register, then add the contents of the register to the other variable in memory.

The processor can access four of the general registers — AX, DX, CX, and BX — either as two 8-bit registers or as a single 16-bit register. The AH, DH, CH, and BH registers represent the high-order 8 bits of the corresponding registers. Similarly, AL, DL, CL, and BL represent the low-order 8 bits of the registers.

The 80386/486 processors can extend all the general registers to 32 bits, though as Figure 1.4 shows, you cannot treat the upper 16 bits as a separate register as you can the lower 16 bits. To use EAX as an example, you can directly reference the low byte as AL, the next lowest byte as AH, and the low word as AX. To access the high word of EAX, however, you must first shift the upper 16 bits into the lower 16 bits.

**Special-Purpose Registers**
The 8086 family of processors has two additional registers, SP and IP, whose values are changed automatically by the processor.

**SP (Stack Pointer)**
The SP register points to the current location within the stack segment. Pushing a value onto the stack decreases the value of SP by two; popping from the stack increases the value of SP by two. Thirty-two-bit operands on 80386/486 processors increase or decrease SP by four instead of two. The CALL and INT instructions store the return address on the stack and reduce SP accordingly. Return instructions retrieve the stored address from the stack and reset SP to its value before the call. SP can also be adjusted with instructions such as ADD. The program stack is described in detail in Chapter 3.
**IP (Instruction Pointer)**
The IP register always contains the address of the next instruction to be executed. You cannot directly access or change the instruction pointer. However, instructions that control program flow (such as calls, jumps, loops, and interrupts) automatically change the instruction pointer.

**Flags Register**
The 16 bits in the flags register control the execution of certain instructions and reflect the current status of the processor. In 80386/486 processors, the flags register is extended to 32 bits. Some bits are undefined, so there are actually 9 flags for real mode, 11 flags (including a 2-bit flag) for 80286 protected mode, 13 for the 80386, and 14 for the 80486. The extended flags register of the 80386/486 is sometimes called “Eflags.”

Figure 1.5 shows the bits of the 32-bit flags register for the 80386/486. Earlier 8086-family processors use only the lower word. The unmarked bits are reserved for processor use, and should not be modified.

![Image of Flags for 8088-80486 Processors](image)

**Figure 1.5** Flags for 8088-80486 Processors

In the following descriptions and throughout this book, “set” means a bit value of 1, and “cleared” means the bit value is 0. The nine flags common to all 8086-family processors, starting with the low-order flags, include:
Flag | Description
--- | ---
Carry | Set if an operation generates a carry to or a borrow from a destination operand.
Parity | Set if the low-order bits of the result of an operation contain an even number of set bits.
Auxiliary Carry | Set if an operation generates a carry to or a borrow from the low-order 4 bits of an operand. This flag is used for binary coded decimal (BCD) arithmetic.
Zero | Set if the result of an operation is 0.
Sign | Equal to the high-order bit of the result of an operation (0 is positive, 1 is negative).
Trap | If set, the processor generates a single-step interrupt after each instruction. A debugging program can use this feature to execute a program one instruction at a time.
Interrupt Enable | If set, interrupts are recognized and acted on as they are received. The bit can be cleared to turn off interrupt processing temporarily.
Direction | If set, string operations process down from high addresses to low addresses. If cleared, string operations process up from low addresses to high addresses.
Overflow | Set if the result of an operation is too large or small to fit in the destination operand.

Although all flags serve a purpose, most programs require only the carry, zero, sign, and direction flags.

**Statements**

Statements are the line-by-line components of source files. Each MASM statement specifies an instruction or directive for the assembler. Statements have up to four fields, as shown here:

\[
\text{name:} [\text{operation}] [\text{operands}] [;\text{comment}]
\]

The following list explains each field:

<table>
<thead>
<tr>
<th>Field</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>Labels the statement, so that instructions elsewhere in the program can refer to the statement by name. The name field can label a variable, type, segment, or code location.</td>
</tr>
<tr>
<td>operation</td>
<td>Defines the action of the statement. This field contains either an instruction or an assembler directive.</td>
</tr>
<tr>
<td>operands</td>
<td>Lists one or more items on which the instruction or directive operates.</td>
</tr>
<tr>
<td>comment</td>
<td>Provides a comment for the programmer. Comments are for documentation only; they are ignored by the assembler.</td>
</tr>
</tbody>
</table>
The following line contains all four fields:

```
mainlp: mov     ax, 7   ; Load AX with the value 7
```

Here, `mainlp` is the label, `mov` is the operation, and `ax` and `7` are the operands, separated by a comma. The comment follows the semicolon.

All fields are optional, although certain directives and instructions require an entry in the name or operand field. Some instructions and directives place restrictions on the choice of operands. By default, MASM is not case sensitive.

Each field (except the comment field) must be separated from other fields by white-space characters (spaces or tabs). MASM also requires code labels to be followed by a colon, operands to be separated by commas, and comments to be preceded by a semicolon.

A logical line can contain up to 512 characters and occupy one or more physical lines. To extend a logical line into two or more physical lines, put the backslash character (\) as the last non-whitespace character before the comment or end of the line. You can place a comment after the backslash as shown in this example:

```
.IFDEF (x > 0) \  ; X must be positive
      && (ax > x) \  ; Result from function must be > x
      && (cx == 0) ; Check loop counter, too
      mov     dx, 20h
.ENDIF
```

Multiline comments can also be specified with the `COMMENT` directive. The assembler ignores all text and code between the delimiters or on the same line as the delimiters. This example illustrates the use of `COMMENT`.

```
COMMENT ^ The assembler
      ignores this text
^ mov     ax, 1 and this code
```

**The Assembly Process**

Creating and running an executable file involves four steps:

1. Assembling the source code into an object file
2. Linking the object file with other modules or libraries into an executable program
3. Loading the program into memory
4. Running the program
Once you have written your assembly-language program, MASM provides several options for assembling it. The `OPTION` directive has several different arguments that let you control the way MASM assembles your programs.

Conditional assembly allows you to create one source file that can generate a variety of programs, depending on the status of various conditional-assembly statements.

**Generating and Running Executable Programs**

This section briefly lists all the actions that take place during each of the assembly steps. You can change the behavior of some of these actions in various ways, such as using macros instead of procedures, or using the `OPTION` directive or conditional assembly. The other chapters in this book include specific programming methods; this section simply gives you an overview.

**Assembling**

The ML.EXE program does two things to create an executable program. First, it assembles the source code into an intermediate object file. Second, it calls the linker, LINK.EXE, which links the object files and libraries into an executable program.

At assembly time, the assembler:

- Evaluates conditional-assembly directives, assembling if the conditions are true.
- Expands macros and macro functions.
- Evaluates constant expressions such as `MYFLAG AND 80H`, substituting the calculated value for the expression.
- Encodes instructions and nonaddress operands. For example, `mov cx, 13` can be encoded at assembly time because the instruction does not access memory.
- Saves memory offsets as offsets from their segments.
- Places segments and segment attributes in the object file.
- Saves placeholders for offsets and segments (relocatable addresses).
- Outputs a listing if requested.
- Passes messages (such as `INCLUDELIB` and `.DOSSEG`) directly to the linker.

For information about conditional assembly, see “Conditional Directives” in this chapter; for macros, see Chapter 9. Further details about segments and offsets are included in Chapters 2 and 3. Assembly listings are explained in Appendix C.
Linking
Once your source code is assembled, the resulting object file is passed to the linker. At this point, the linker may combine several object files into an executable program. The linker:

- Combines segments according to the instructions in the object files, rearranging the positions of segments that share the same class or group.
- Fills in placeholders for offsets (relocatable addresses).
- Writes relocations for segments into the header of .EXE files (but not .COM files).
- Writes the result as an executable program file.

Classes and groups are defined in “Defining Segment Groups” in Chapter 2. Segments and offsets are explained in Chapter 3, “Using Addresses and Pointers.”

Loading
After loading the executable file into memory, the operating system:

- Creates the program segment prefix (PSP) header in memory.
- Allocates memory for the program, based on the values in the PSP.
- Loads the program.
- Calculates the correct values for absolute addresses from the relocation table.
- Loads the segment registers SS, CS, DS, and ES with values that point to the proper areas of memory.

For information about segment registers, the instruction pointer (IP), and the stack pointer (SP), see “Registers” earlier in this chapter. For more information on the PSP see Help or an MS-DOS reference.

Running
To run your program, MS-DOS jumps to the program’s first instruction. Some program operations, such as resolving indirect memory operands, cannot be handled until the program runs. For a description of indirect references, see “Indirect Operands” in Chapter 7.

Using the OPTION Directive
The OPTION directive lets you modify global aspects of the assembly process. With OPTION, you can change command-line options and default arguments. These changes affect only statements that follow the OPTION keyword.
For example, you may have MASM code in which the first character of a variable, macro, structure, or field name is a dot (.). Since a leading dot causes MASM 6.1 to generate an error, you can use this statement in your program:

```
OPTION DOTNAME
```

This enables the use of the dot for the first character.

Changes made with `OPTION` override any corresponding command-line option. For example, suppose you compile a module with this command line (which enables M510 compatibility):

```
ML /Zm TEST.ASM
```

The assembler disables M510 compatibility options for all code following this statement:

```
OPTION NOM510
```

The following lists explain each of the arguments for the `OPTION` directive. Where appropriate, an underline identifies the default argument. If you wish to place more than one `OPTION` statement on a line, separate them by commas.

Options for M510 compatibility include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CASEMAP: maptype</td>
<td>CASEMAP:NONE (or /Cx) causes internal symbol recognition to be case sensitive and causes the case of identifiers in the .OBJ file to be the same as specified in the EXTERNDEF, PUBLIC, or COMM statement. The default is CASEMAP:NOPUBLIC (or /Cp). It specifies case insensitivity for internal symbol recognition and the same behavior as CASEMAP:NONE for case of identifiers in .OBJ files. CASEMAP:ALL (/Cu) specifies case insensitivity for identifiers and converts all identifier names to uppercase.</td>
</tr>
<tr>
<td>DOTNAME</td>
<td>Enables the use of the dot (.) as the leading character in variable, macro, structure, union, and member names.</td>
</tr>
<tr>
<td>M510</td>
<td>Sets all features to be compatible with MASM version 5.1, disabling the SCOPED argument and enabling OLDMACROS, DOTNAME, and, OLDSTRUCTS. <code>OPTION M510</code> conditionally sets other arguments for the <code>OPTION</code> directive. For more information on using <code>OPTION M510</code>, see Appendix A.</td>
</tr>
</tbody>
</table>
Argument Description

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>OLDMACROS</td>
<td>NOOLDMACROS</td>
</tr>
<tr>
<td>OLDSTRUCTS</td>
<td>NOOLDSTRUCTS</td>
</tr>
<tr>
<td>SCOPED</td>
<td>NOSCOPED</td>
</tr>
<tr>
<td>SETIF2: TRUE</td>
<td>FALSE</td>
</tr>
</tbody>
</table>

Options for procedure use include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>LANGUAGE: langtype</td>
<td>Specifies the default language type (C, PASCAL, FORTRAN, BASIC, SYSCALL, or STDCALL) to be used with PROC, EXTERN, and PUBLIC. This use of the OPTION directive overrides the .MODEL directive but is normally used when .MODEL is not given.</td>
</tr>
<tr>
<td>EPILOGUE: macroname</td>
<td>Instructs the assembler to call the macroname to generate a user-defined epilogue instead of the standard epilogue code when a RET instruction is encountered. See Chapter 7.</td>
</tr>
<tr>
<td>PROLOGUE: macroname</td>
<td>Instructs the assembler to call macroname to generate a user-defined prologue instead of generating the standard prologue code. See Chapter 7.</td>
</tr>
<tr>
<td>PROC: visibility</td>
<td>Lets you explicitly set the default visibility as PUBLIC, EXPORT, or PRIVATE.</td>
</tr>
</tbody>
</table>

Other options include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>EXPR16</td>
<td>Sets the expression word size to 16 or 32 bits. The default is 32 bits. The M510 argument to the OPTION directive sets the word size to 16 bits. Once set with the OPTION directive, the expression word size cannot be changed.</td>
</tr>
<tr>
<td>Argument</td>
<td>Description</td>
</tr>
<tr>
<td>------------------------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>**EMULATOR</td>
<td>NOEMULATOR**</td>
</tr>
<tr>
<td>**LJMP</td>
<td>NOLJMP**</td>
</tr>
<tr>
<td><strong>NOKEYWORD:&lt;keywordlist&gt;</strong></td>
<td>Disables the specified reserved words. For an example of the syntax for this argument, see “Reserved Words” in this chapter.</td>
</tr>
<tr>
<td><strong>NOSIGNEXTEND</strong></td>
<td>Overrides the default sign-extended opcodes for the <strong>AND</strong>, <strong>OR</strong>, and <strong>XOR</strong> instructions and generates the larger non-sign-extended forms of these instructions. Provided for compatibility with NEC V25 and NEC V35 controllers.</td>
</tr>
<tr>
<td><strong>OFFSET:offertype</strong></td>
<td>Determines the result of <strong>OFFSET</strong> operator fixups. <strong>SEGMENT</strong> sets the defaults for fixups to be segment-relative (compatible with MASM 5.1). <strong>GROUP</strong>, the default, generates fixups relative to the group (if the label is in a group). <strong>FLAT</strong> causes fixups to be relative to a flat frame. (The .386 mode must be enabled to use <strong>FLAT</strong>.) See Appendix A.</td>
</tr>
<tr>
<td>**READONLY</td>
<td>NOREADONLY**</td>
</tr>
<tr>
<td><strong>SEGMENT:segSize</strong></td>
<td>Allows global default segment size to be set. Also determines the default address size for external symbols defined outside any segment. The <strong>segSize</strong> can be USE16, USE32, or FLAT.</td>
</tr>
</tbody>
</table>
Conditional Directives

MASM 6.1 provides conditional-assembly directives and conditional-error directives. Conditional-assembly directives let you test for a specified condition and assemble a block of statements if the condition is true. Conditional-error directives allow you to test for a specified condition and generate an assembly error if the condition is true.

Both kinds of conditional directives test assembly-time conditions, not run-time conditions. You can test only expressions that evaluate to constants during assembly. For a list of the predefined symbols often used in conditional assembly, see “Predefined Symbols,” earlier in this chapter.

Conditional-Assembly Directives

The IF and ENDIF directives enclose the conditional statements. The optional ELSEIF and ELSE blocks follow the IF directive. There are many forms of the IF and ELSE directives. Help provides a complete list.

The following statements show the syntax for the IF directives. The syntax for other condition-assembly directives follow the same form.

```
IF expression1
ifstatements
[[ELSEIF expression2
elseifstatements]]
[[ELSE
elsestatements]]
ENDIF
```

The statements within an IF block can be any valid instructions, including other conditional blocks, which in turn can contain any number of ELSEIF blocks. ENDIF ends the block.

MASM assembles the statements following the IF directive only if the corresponding condition is true. If the condition is not true and the block contains an ELSEIF directive, the assembler checks to see if the corresponding condition is true. If so, it assembles the statements following the ELSEIF directive. If no IF or ELSEIF conditions are satisfied, the assembler processes only the statements following the ELSE directive.

For example, you may want to assemble a line of code only if your program defines a particular variable. In this example,

```
IFDEF buffer
buff BYTE buffer DUP(?)
ENDIF
```

the assembler allocates buff only if buffer has been previously defined.
MASM 6.1 provides the directives `IF1`, `IF2`, `ELSEIF1`, and `ELSIF2` to grant assembly only on pass one or pass two. To use these directives, you must either enable 5.1 compatibility (with the `/Zm` command-line switch or `OPTION M510`) or set `OPTION SETIF2:TRUE`, as described in the previous section.

The following list summarizes the conditional-assembly directives:

<table>
<thead>
<tr>
<th>The Directive</th>
<th>Grants Assembly If</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>IF expression</code></td>
<td><code>expression</code> is true (nonzero)</td>
</tr>
<tr>
<td><code>IFE expression</code></td>
<td><code>expression</code> is false (zero)</td>
</tr>
<tr>
<td><code>IFDEF name</code></td>
<td><code>name</code> has been previously defined</td>
</tr>
<tr>
<td><code>IFNDEF name</code></td>
<td><code>name</code> has not been previously defined</td>
</tr>
<tr>
<td><code>IFB argument*</code></td>
<td><code>argument</code> is blank</td>
</tr>
<tr>
<td><code>IFNB argument*</code></td>
<td><code>argument</code> is not blank</td>
</tr>
<tr>
<td><code>IFIDN[I] arg1, arg2*</code></td>
<td><code>arg1 equals arg2</code></td>
</tr>
<tr>
<td><code>IFDIF[I] arg1, arg2*</code></td>
<td><code>arg1 does not equal arg2</code></td>
</tr>
</tbody>
</table>

The optional `I` suffix (`IFIDNI` and `IFDIFI`) makes comparisons insensitive to differences in case.

* Used only in macros.

**Conditional-Error Directives**

You can use conditional-error directives to debug programs and check for assembly-time errors. By inserting a conditional-error directive at a key point in your code, you can test assembly-time conditions at that point. You can also use conditional-error directives to test for boundary conditions in macros.

Like other severe errors, those generated by conditional-error directives cause the assembler to return a nonzero exit code. If MASM encounters a severe error during assembly, it does not generate the object module.

For example, the `.ERRNDEF` directive produces an error if the program has not defined a given label. In the following example, `.ERRNDEF` makes sure a label called `publ evel` actually exists.

```
.PUBLI C  var1, var2
ELSE
.PUBLI C  var1, var2, var3
ENDIF
```

The conditional-error directives use the syntax given in the previous section. The following list summarizes the conditional-error directives. Note their close correspondence with the previous list of conditional-assembly directives.
The Directive | Generates an Error
---|---
.ERR | Unconditionally where it occurs in the source file. Usually placed within a conditional-assembly block.
.ERRE expression | If expression is false (zero).
.ERRNZ expression | If expression is true (nonzero).
.ERRDEF name | If name has been defined.
.ERRNDEF name | If name has not been defined.
.ERRB argument* | If argument is blank.
.ERRNB argument* | If argument is not blank.
.ERRIDN[I] arg1, arg2* | If arg1 equals arg2.
.ERRDIF[I] arg1, arg2* | If arg1 does not equal arg2.

* Used only in macros

Two special conditional-error directives, .ERR1 and .ERR2, generate an error only on pass one or pass two. To use these directives, you must either enable 5.1 compatibility (with the /Zm command-line switch or OPTION M510) or set OPTION SETIF2:TRUE, as described in the previous section.
CHAPTER 2

Organizing Segments

Understanding segments is an essential part of programming in assembly language. In the family of 8086-based processors, the term segment has two meanings:

- A block of memory of discrete size, called a “physical segment.” The number of bytes in a physical memory segment is 64K for 16-bit processors or 4 gigabytes for 32-bit processors.
- A variable-sized block of memory, called a “logical segment,” occupied by a program’s code or data.

As you read this chapter, the distinction between the two definitions will become clear. The adjectives “physical” and “logical” are not often used when speaking of segments. The beginning programmer is left to infer from context which definition applies. Fortunately, this is not difficult, and a distinction is often not required.

This chapter begins with a close look at physical memory segments. This lays the foundation for understanding logical segments, which form the subject of most of the following sections.

The section “Using Simplified Segment Directives” explains how to begin, end, and organize segments. It also explains how to access far data and code with simplified segment directives.

The next section, “Using Full Segment Definitions,” describes how to order, combine, and divide segments, and how to use the SEGMENT directive to define full segments. It also explains how to create a segment group so that you can use one segment address to access all the data.

Most of the information in this chapter also applies to writing modules to be called from other programs. Exceptions are noted when they apply. For more information about multiple-module programming, see Chapter 8, “Sharing Data and Procedures Among Modules and Libraries.”
Physical Memory Segments

As explained in Chapter 1, a physical segment can begin only at memory locations evenly divisible by 16, including address 0. Intel calls such locations “paragraphs.” You can easily recognize a paragraph location because its hexadecimal address always ends with 0, as in 10000h or 2EA70h. The 8086/286 processors allow segments 64K in size, the largest number 16 bits can represent. The 80386/486 processors still adhere to the 64K limit when running in real mode. In protected mode, however, they use 32-bit registers that can hold addresses up to 4 gigabytes.

Segmented architecture presents certain hurdles for the assembly-language programmer. For small programs, the limitations lose importance. Code and data each occupy less than 64K and reside in individual segments. A simple offset locates each variable or instruction within a segment. Larger programs, however, must contend with problems of segmented memory areas. If data occupies two or more segments, the program must specify both segment and offset to access a variable. When the data forms a continuous stream across segments—such as the text in a word processor’s workspace—the problems become more acute. Whenever it adds or deletes text in the first segment, the word processor must seamlessly move data back and forth over the boundaries of each following segment.

The problem of segment boundaries disappears in the so-called flat address space of 32-bit protected mode. Although segments still exist, they easily hold all the code and data of the largest programs. Even a very large program becomes in effect a small application, able to reach all code and data with a single offset address.

Logical Segments

Logical segments contain the three components of a program: code, data, and stack. MASM organizes the three parts for you so they occupy physical segments of memory. The segment registers CS, DS, and SS contain the addresses of the physical memory segments where the logical segments reside.

You can define segments in two ways: with simplified segment directives and with full segment definitions. You can also use both kinds of segment definitions in the same program.

Simplified segment directives hide many of the details of segment definition and assume the same conventions used by Microsoft high-level languages. (See the following section, “Using Simplified Segment Directives.”) The simplified segment directives generate necessary code, specify segment attributes, and arrange segment order.
Full segment definitions require more complex syntax but provide more complete control over how the assembler generates segments. (See “Using Full Segment Definitions” later in this chapter.) If you use full segment definitions, you must write code to handle all the tasks performed automatically by the simplified segment directives.

Using Simplified Segment Directives

Structuring a MASM program using simplified segments requires use of several directives to assign standard names, alignment, and attributes to the segments in your program. These directives define the segments in such a way that linking with Microsoft high-level languages is easy.

The simplified segment directives are .MODEL, .CODE, .CONST, .DATA, .DATA?, .FARDATA, .FARDATA?, .STACK, .STARTUP, and .EXIT. The following sections discuss these directives and the arguments they take.

MASM programs consist of modules made up of segments. Every program written only in MASM has one main module, where program execution begins. This main module can contain code, data, or stack segments defined with all of the simplified segment directives. Any additional modules should contain only code and data segments. Every module that uses simplified segments must, however, begin with the .MODEL directive.

The following example shows the structure of a main module using simplified segment directives. It uses the default processor (8086) and the default stack distance (NEARSTACK). Additional modules linked to this main program would use only the .MODEL, .CODE, and .DATA directives and the END statement.
; This is the structure of a main module
; using simplified segment directives

.MODEL small, c ; This statement is required before you
; can use other simplified segment directives

.STACK ; Use default 1-kilobyte stack

.DATA ; Begin data segment
; Place data declarations here

.CODE ; Begin code segment

.STARTUP ; Generate start-up code
; Place instructions here

.EXIT ; Generate exit code

END

The .DATA and .CODE statements do not require any separate statements to
define the end of a segment. They close the preceding segment and then open a
new segment. The .STACK directive opens and closes the stack segment but
does not close the current segment. The END statement closes the last segment
and marks the end of the source code. It must be at the end of every module.

Defining Basic Attributes with .MODEL

The .MODEL directive defines the attributes that affect the entire module:
memory model, default calling and naming conventions, operating system, and
stack type. This directive enables use of simplified segments and controls the
name of the code segment and the default distance for procedures.

You must place .MODEL in your source file before any other simplified
segment directive. The syntax is:

.MODEL memorymodel [, modeloptions ]

The memorymodel field is required and must appear immediately after the
.MODEL directive. The use of modeloptions, which define the other attributes,
is optional. The modeloptions must be separated by commas. You can also use
equates passed from the ML command line to define the modeloptions.

The following list summarizes the memorymodel field and the modeloptions
fields, which specify language and stack distance:
### Field Description

<table>
<thead>
<tr>
<th>Field</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Memory model</td>
<td><strong>TINY, SMALL, COMPACT, MEDIUM, LARGE, HUGE, or FLAT.</strong> Determines size of code and data pointers. This field is required.</td>
</tr>
<tr>
<td>Language</td>
<td><strong>C, BASIC, FORTRAN, PASCAL, SYSCALL, or STDCALL.</strong> Sets calling and naming conventions for procedures and public symbols.</td>
</tr>
<tr>
<td>Stack distance</td>
<td><strong>NEARSTACK</strong> or <strong>FARSTACK.</strong> Specifying <strong>NEARSTACK</strong> groups the stack segment into a single physical segment (DGROUP) along with data. SS is assumed to equal DS. <strong>FARSTACK</strong> does not group the stack with DGROUP; thus SS does not equal DS.</td>
</tr>
</tbody>
</table>
You can use no more than one reserved word from each field. The following examples show how you can combine various fields:

```
.MODEL small            ; Small memory model
.MODEL large, c, farstack    ; Large memory model, 
                                ; C conventions,
                                ; separate stack
.MODEL medium pascal        ; Medium memory model,
                                ; Pascal conventions,
                                ; near stack (default)
```

The next four sections give more detail on each field.

**Defining the Memory Model**

MASM supports the standard memory models used by Microsoft high-level languages—tiny, small, medium, compact, large, huge, and flat. You specify the memory model with attributes of the same name placed after the `.MODEL` directive. With the exception of the flat model, which requires instructions specific to the 80386/486, your choice of a memory model does not limit the kind of instructions you can write. The memory model does, however, control segment defaults and determine whether data and code are near or far by default, as indicated in the following table.

<table>
<thead>
<tr>
<th>Memory Model</th>
<th>Default Code</th>
<th>Default Data</th>
<th>Operating System</th>
<th>Data and Code Combined</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tiny</td>
<td>Near</td>
<td>Near</td>
<td>MS-DOS</td>
<td>Yes</td>
</tr>
<tr>
<td>Small</td>
<td>Near</td>
<td>Near</td>
<td>MS-DOS, Windows</td>
<td>No</td>
</tr>
<tr>
<td>Medium</td>
<td>Far</td>
<td>Near</td>
<td>MS-DOS, Windows</td>
<td>No</td>
</tr>
<tr>
<td>Compact</td>
<td>Near</td>
<td>Far</td>
<td>MS-DOS, Windows</td>
<td>No</td>
</tr>
<tr>
<td>Large</td>
<td>Far</td>
<td>Far</td>
<td>MS-DOS, Windows</td>
<td>No</td>
</tr>
<tr>
<td>Huge</td>
<td>Far</td>
<td>Far</td>
<td>MS-DOS, Windows</td>
<td>No</td>
</tr>
<tr>
<td>Flat</td>
<td>Near</td>
<td>Near</td>
<td>Windows NT</td>
<td>Yes</td>
</tr>
</tbody>
</table>

When writing assembler modules for a high-level language, you should use the same memory model as the calling language. Choose the smallest memory model available that can contain your data and code, since near references operate more efficiently than far references.

The predefined symbol `@Model` returns the memory model, encoding memory models as integers 1 through 7. For more information on predefined symbols, see “Predefined Symbols” in Chapter 1. For an example of how to use them, see Help.
The seven memory models supported by MASM 6.1 fall into three groups, described in the following paragraphs.

Small, Medium, Compact, Large, and Huge Models
The traditional memory models recognized by many languages are small, medium, compact, large, and huge. Small model supports one data segment and one code segment. All data and code are near by default. Large model supports multiple code and multiple data segments. All data and code are far by default. Medium and compact models are in-between. Medium model supports multiple code and single data segments; compact model supports multiple data segments and a single code segment.

Huge model implies individual data items larger than a single segment, but the implementation of huge data items must be coded by the programmer. Since the assembler provides no direct support for this feature, huge model is essentially the same as large model.

In each of these models, you can override the default. For example, you can make large data items far in small model, or internal procedures near in large model.

Tiny Model
Tiny-model programs run only under MS-DOS. Tiny model places all data and code in a single segment. Therefore, the total program file size can occupy no more than 64K. The default is near for code and static data items; you cannot override this default. However, you can allocate far data dynamically at run time using MS-DOS memory allocation services.

Tiny model produces MS-DOS .COM files. Specifying .MODEL tiny automatically sends the /TINY argument to the linker. Therefore, the /AT argument is not necessary with .MODEL tiny. However, /AT does not insert a .MODEL directive. It only verifies that there are no base or pointer fixups, and sends /TINY to the linker.

Flat Model
The flat memory model is a nonsegmented configuration available in 32-bit operating systems. It is similar to tiny model in that all code and data go in a single 32-bit segment.

To write a flat model program, specify the .386 or .486 directive before .MODEL FLAT. All data and code (including system resources) are in a single 32-bit segment. The operating system automatically initializes segment registers at load time; you need to modify them only when mixing 16-bit and 32-bit segments in a single application. CS, DS, ES, and SS all occupy the supergroup FLAT. Addresses and pointers passed to system services are always 32-bit near addresses and pointers.
Choosing the Language Convention

The language option facilitates compatibility with high-level languages by determining the internal encoding for external and public symbol names, the code generated for procedure initialization and cleanup, and the order that arguments are passed to a procedure with INVOKE. It also facilitates compatibility with high-level language modules. The PASCAL, BASIC, and FORTRAN conventions are identical. C and SYSCALL have the same calling convention but different naming conventions. Functions in the Windows API use the Pascal calling convention.

Procedure definitions (PROC) and high-level procedure calls (INVOKE) automatically generate code consistent with the calling convention of the specified language. The PROC, INVOKE, PUBLIC, and EXTERN directives all use the naming convention of the language. These directives follow the default language conventions from the .MODEL directive unless you specifically override the default. Use of these directives is explained in “Controlling Program Flow,” Chapter 7. You can also use the OPTION directive to set the language type. (See “Using the OPTION Directive” in Chapter 1.) Not specifying a language type in either the .MODEL, OPTION, EXTERN, PROC, INVOKE, or PROTO statement causes the assembler to generate an error.

The predefined symbol @Interface provides information about the language parameters. For a description of the bit flags, see Help.

For more information on calling and naming conventions, see Chapter 12, “Mixed-Language Programming.” For information about writing procedures and prototypes, see Chapter 7, “Controlling Program Flow.” For information on multiple-module programming, refer to Chapter 8, “Sharing Data and Procedures Among Modules and Libraries.”

Setting the Stack Distance

The NEARSTACK keyword places the stack segment in the group DGROUP along with the data segment. The .STARTUP directive then generates code to adjust SS:SP so that SS (Stack Segment register) holds the same address as DS (Data Segment register). If you do not use .STARTUP, you must make this adjustment or your program may fail to run. (For information about startup code, see “Starting and Ending Code with .STARTUP and .EXIT,” later in this chapter.) In this case, you can use DS to access stack items (including parameters and local variables) and SS to access near data. Furthermore, since stack items share the same segment address as near data, you can reliably pass near pointers to stack items.

The FARSTACK setting gives the stack a segment of its own. That is, SS does not equal DS. The default stack type, NEARSTACK, is a convenient setting for
most programs. Use **FARSTACK** for special cases such as memory-resident programs.
and dynamic-link libraries (discussed in Chapters 10 and 11) when you cannot assume that the caller’s stack is near. You can use the predefined symbol @Stack to determine if the stack location is DGROUP (for near stacks) or STACK (for far stacks).

Specifying a Processor and Coprocessor

MASM supports a set of directives for selecting processors and coprocessors. Once you select a processor, you must use only the instruction set for that processor. The default is the 8086 processor. If you always want your code to run on this processor, you do not need to add any processor directives.

To enable a different processor mode and the additional instructions available on that processor, use the directives .186, .286, .386, and .486. The instruction timings on a listing (see Appendix C, “Generating and Reading Assembly Listings”) correspond to whichever processor directive you select.

The .286P, .386P, and .486P directives enable the instructions available only at higher privilege levels in addition to the normal instruction set for the given processor. Generally, you don’t need privileged instructions unless you are writing operating-systems code or device drivers.

In addition to enabling different instruction sets, the processor directives also affect the behavior of extended language features. For example, the INVOKE directive pushes arguments onto the stack. If the .286 directive is in effect, INVOKE takes advantage of operations possible only on 80286 and later processors.

Use the directives .8087 (the default), .287, .387, and .NO87 to select a math coprocessor instruction set. The .NO87 directive turns off assembly of all coprocessor instructions. Note that .486 also enables assembly of all coprocessor instructions because the 80486 processor has a complete set of coprocessor registers and instructions built into the chip. The processor instructions imply the corresponding coprocessor directive. The coprocessor directives are provided to override the defaults.

Creating a Stack

The stack is the section of memory used for pushing or popping registers and storing the return address when a subroutine is called. The stack often holds temporary and local variables.

If your main module is written in a high-level language, that language handles the details of creating a stack. Use the .STACK directive only when you write a main module in assembly language.
The .STACK directive creates a stack segment. By default, the assembler allocates 1K of memory for the stack. This size is sufficient for most small programs.
To create a stack of a size other than the default size, give `.STACK` a single numeric argument indicating stack size in bytes:

```
.STACK 2048 ; Use 2K stack
```

For a description of how stack memory is used with procedure calls and local variables, see Chapter 7, “Controlling Program Flow.”

Creating Data Segments

Programs can contain both near and far data. In general, you should place important and frequently used data in the near data area, where data access is faster. This area can get crowded, however, because in 16-bit operating systems the total amount of all near data in all modules cannot exceed 64K. Therefore, you may want to place infrequently used or particularly large data items in a far data segment.

The `.DATA`, `.DATA?`, `.CONST`, `.FARDATA`, and `.FARDATA?` directives create data segments. You can access the various segments within DGROUP without reloading segment registers (see “Defining Segment Groups,” later in this chapter). These five directives also prevent instructions from appearing in data segments by assuming CS to `ERROR`.

Near Data Segments

The `.DATA` directive creates a near data segment. This segment contains the frequently used data for your program. It can occupy up to 64K in MS-DOS or 512 megabytes under flat model in Windows NT. It is placed in a special group identified as DGROUP, which is also limited to 64K.

When you use `.MODEL`, the assembler automatically defines DGROUP for your near data segment. The segments in DGROUP form near data, which can normally be accessed directly through DS or SS.

You can also define the `.DATA?` and `.CONST` segments that go into DGROUP unless you are using flat model. Although all of these segments (along with the stack) are eventually grouped together and handled as data segments, `.DATA?` and `.CONST` enhance compatibility with Microsoft high-level languages. In Microsoft languages, `.CONST` is used to define constant data such as strings and floating-point numbers that must be stored in memory. The `.DATA?` segment is used for storing uninitialized variables. You can follow this convention if you want. If you use C startup code, `.DATA?` is initialized to 0.

You can use `@data` to determine the group of the data segment and `@DataSize` to determine the size of the memory model set by the `.MODEL` directive. The predefined symbols `@WordSize` and `@CurSeg` return the size attribute and name of the current segment, respectively. See “Predefined Symbols” in Chapter 1.
Far Data Segments

The compact, large, and huge memory models use far data addresses by default. With these memory models, however, you can still construct data segments using .DATA, .DATA?, and .CONST. The effect of these directives does not change from one memory model to the next. They always contribute segments to the default data area, DGROUP, which has a total limit of 64K.

When you use .FARDATA or .FARDATA? in the small and medium memory models, the assembler creates far data segments FAR_DATA and FAR_BSS, respectively. You can access variables with:

```
mov ax, SEG farvar2
mov ds, ax
```

For more information on far data, see “Near and Far Addresses” in Chapter 3.

Creating Code Segments

Whether you are writing a main module or a module to be called from another module, you can have both near and far code segments. This section explains how to use near and far code segments and how to use the directives and predefined equates that relate to code segments.

Near Code Segments

The small memory model is often the best choice for assembly programs that are not linked to modules in other languages, especially if you do not need more than 64K of code. This memory model defaults to near (two-byte) addresses for code and data, which makes the program run faster and use less memory.

When you use .MODEL and simplified segment directives, the .CODE directive in your program instructs the assembler to start a code segment. The next segment directive closes the previous segment; the END directive at the end of your program closes remaining segments. The example at the beginning of “Using Simplified Segment Directives,” earlier in this chapter, shows how to do this.

You can use the predefined symbol @CodeSize to determine whether code pointers default to NEAR or FAR.

Far Code Segments

When you need more than 64K of code, use the medium, large, or huge memory model to create far segments.

The medium, large, and huge memory models use far code addresses by default. In the larger memory models, the assembler creates a different code segment for each module. If you use multiple code segments in the small,
compact, or tiny model, the linker combines the .CODE segments for all modules into one segment.

For far code segments, the assembler names each code segment MODNAME_TEXT, in which MODNAME is the name of the module. With near code, the assembler names every code segment _TEXT, causing the linker to concatenate these segments into one. You can override the default name by providing an argument after .CODE. (For a complete list of segment names generated by MASM, see Appendix E, “Default Segment Names.”)

With far code, a single module can contain multiple code segments. The .CODE directive takes an optional text argument that names the segment. For instance, the following example creates two distinct code segments, FIRST_TEXT and SECOND_TEXT.

```
.CODE   FIRST
.
; First set of instructions here
.
.CODE   SECOND
.
; Second set of instructions here
```

Whenever the processor executes a far call or jump, it loads CS with the new segment address. No special action is necessary other than making sure that you use far calls and jumps. See “Near and Far Addresses” in Chapter 3.

**Note** The assembler always assumes that the CS register contains the address of the current code segment or group.

### Starting and Ending Code with .STARTUP and .EXIT

The easiest way to begin and end an MS-DOS program is to use the .STARTUP and .EXIT directives in the main module. The main module contains the starting point and usually the termination point. You do not need these directives in a module called by another module.

These directives make MS-DOS programs easy to maintain. They automatically generate code appropriate to the stack distance specified with .MODEL. However, they do not apply to flat-model programs written for 32-bit operating systems. Thus, you should not use .STARTUP or .EXIT in programs written for Windows NT.
To start a program, place the `.STARTUP` directive where you want execution to begin. Usually, this location immediately follows the `.CODE` directive:

```assembly
.CODE
.STARTUP

; Place executable code here

.EXIT
END
```

Note that `.EXIT` generates executable code, while `END` does not. The `END` directive informs the assembler that it has reached the end of the module. All modules must end with the `END` directive whether you use simplified or full segments.

If you do not use `.STARTUP`, you must give the starting address as an argument to the `END` directive. For example, the following fragment shows how to identify a program’s starting instruction with the label `start`:

```assembly
.CODE
.start:

; Place executable code here

.END start
```

Only the `END` directive for the module with the starting instruction should have an argument. When `.STARTUP` is present, the assembler ignores any argument to `END`.

For the default `NEARSTACK` attribute, `.STARTUP` points DS to DGROUP and sets SS:SP relative to DGROUP, generating the following code:
@Startup:

    mov     dx, DGROUP
    mov     ds, dx
    mov     bx, ss
    sub     bx, dx
    shl     bx, 1           ; If .286 or higher, this is
    shl     bx, 1           ;    shortened to shl bx, 4
    shl     bx, 1
    shl     bx, 1
    cli                     ; Not necessary in .286 or higher
    mov     ss, dx
    add     sp, bx
    sti                     ; Not necessary in .286 or higher
    ..
    ..

END     @Startup

An MS-DOS program with the FARSTACK attribute does not need to adjust
SS:SP, so .STARTUP just initializes DS, like this:

@Startup:

    mov     dx, DGROUP
    mov     ds, dx
    ..
    ..

END     @Startup

When the program terminates, you can return an exit code to the operating
system. Applications that check exit codes usually assume that an exit code of 0
means no problem occurred, and that an exit code of 1 means an error
terminated the program. The .EXIT directive accepts a 1-byte exit code as its
optional argument:

    .EXIT   1               ; Return exit code 1

.EXIT generates the following code that returns control to MS-DOS, thus
terminating the program. The return value, which can be a constant, memory
reference, or 1-byte register, goes into AL:

    mov     al, value
    mov     ah, 04Ch
    int     21h

If your program does not specify a return value, .EXIT returns whatever value
happens to be in AL.
Using Full Segment Definitions

If you need complete control over segments, you can fully define the segments in your program. This section explains segment definitions, including how to order segments and how to define the segment types.

If you write a program under MS-DOS without .MODEL and .STARTUP, you must initialize registers yourself and use the END directive to indicate the starting address. The Windows operating system does not require you to initialize registers, as described in Chapter 3. For a description of typical startup code, see “Controlling the Segment Order,” later in this chapter.

Defining Segments with the SEGMENT Directive

A defined segment begins with the SEGMENT directive and ends with the ENDS directive:

```
name SEGMENT [[align]] [[READONLY]] [[combine]] [[use]] ["class"]
statements
name ENDS
```

The name defines the name of the segment. Within a module, all segment definitions with the same name are treated as though they reference the same segment. The linker also combines identically named segments from different modules unless the combine type is PRIVATE. In addition, segments can be nested.

The optional types that follow the SEGMENT directive give the linker and the assembler instructions on how to set up and combine segments. The optional types, which are explained in detail in the following sections, include:

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>align</td>
<td>Defines the memory boundary on which a new segment begins.</td>
</tr>
<tr>
<td>READONLY</td>
<td>Tells the assembler to report an error if it detects an instruction modiﬁling any item in a READONLY segment.</td>
</tr>
<tr>
<td>combine</td>
<td>Determines how the linker combines segments from different modules when building executable ﬁles.</td>
</tr>
<tr>
<td>use</td>
<td>Determines the size of a segment. USE16 indicates that offsets in the segment are 16 bits wide. USE32 indicates 32-bit offsets.</td>
</tr>
<tr>
<td>class</td>
<td>Provides a class name for the segment. The linker automatically groups segments of the same class in memory.</td>
</tr>
</tbody>
</table>

Types can be specified in any order. You can specify only one attribute from each of these ﬁelds; for example, you cannot have two different align types.
You can close a segment and reopen it later with another SEGMENT directive. When you reopen a segment, you need only give the segment name. You cannot change the attributes of a segment once you have defined it.

Note The PAGE align type and the PUBLIC combine type are distinct from the PAGE and PUBLIC directives. The assembler distinguishes them by means of context.

### Aligning Segments

The optional align type in the SEGMENT directive defines the range of memory addresses from which a starting address for the segment can be selected. The align type can be any of the following:

<table>
<thead>
<tr>
<th>Align Type</th>
<th>Starting Address</th>
</tr>
</thead>
<tbody>
<tr>
<td>BYTE</td>
<td>Next available byte address.</td>
</tr>
<tr>
<td>WORD</td>
<td>Next available word address.</td>
</tr>
<tr>
<td>DWORD</td>
<td>Next available doubleword address.</td>
</tr>
<tr>
<td>PARA</td>
<td>Next available paragraph address (16 bytes per paragraph). Default.</td>
</tr>
<tr>
<td>PAGE</td>
<td>Next available page address (256 bytes per page).</td>
</tr>
</tbody>
</table>

The linker uses the alignment information to determine the relative starting address for each segment. The operating system calculates the actual starting address when the program is loaded.

### Making Segments Read-Only

The optional READONLY attribute is helpful when creating read-only code segments for protected mode, or when writing code to be placed in read-only memory (ROM). It protects against illegal self-modifying code.

The READONLY attribute causes the assembler to check for instructions that modify the segment and to generate an error if it finds any. The assembler generates an error if you attempt to write directly to a read-only segment.

### Combining Segments

The optional combine type in the SEGMENT directive defines how the linker combines segments having the same name but appearing in different modules.
The *combine* type controls linker behavior, not assembler behavior. The *
combine* types, which are described in full detail in Help, include:

<table>
<thead>
<tr>
<th>Combine Type</th>
<th>Linker Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRIVATE</td>
<td>Does not combine the segment with segments from other modules, even if they have the same name. Default.</td>
</tr>
<tr>
<td>PUBLIC</td>
<td>Concatenates all segments having the same name to form a single, contiguous segment.</td>
</tr>
<tr>
<td>STACK</td>
<td>Concatenates all segments having the same name and causes the operating system to set SS:00 to the bottom and SS:SP to the top of the resulting segment. Data initialization is unreliable, as discussed following.</td>
</tr>
<tr>
<td>COMMON</td>
<td>Overlaps segments. The length of the resulting area is the length of the largest of the combined segments. Data initialization is unreliable, as discussed following.</td>
</tr>
<tr>
<td>MEMORY</td>
<td>Used as a synonym for the <em>PUBLIC</em> <em>combine</em> type.</td>
</tr>
<tr>
<td>AT address</td>
<td>Assumes <em>address</em> as the segment location. An AT segment cannot contain any code or initialized data, but is useful for defining structures or variables that correspond to specific far memory locations, such as a screen buffer or low memory. You cannot use the AT <em>combine</em> type in protected-mode programs.</td>
</tr>
</tbody>
</table>

Do not place initialized data in STACK or COMMON segments. With these *combine* types, the linker overlays initialized data for each module at the beginning of the segment. The last module containing initialized data writes over any data from other modules.

**Note** Normally, you should provide at least one stack segment (having STACK *combine* type) in a program. If no stack segment is declared, LINK displays a warning message. You can ignore this message if you have a specific reason for not declaring a stack segment. For example, you would not have a separate stack segment in a MS-DOS tiny model (.COM) program, nor would you need a separate stack in a DLL that uses the caller’s stack.

**Setting Segment Word Sizes (80386/486 Only)**

The *use* type in the *SEGMENT* directive specifies the segment word size on the 80386/486 processors. Segment word size determines the default operand and address size of all items in a segment.

The *size* attribute can be USE16, USE32, or FLAT. If you specify the .386 or .486 directive before the .MODEL directive, USE32 is the default. This attribute specifies that items in the segment are addressed with a 32-bit offset rather than a
16-bit offset. If .MODEL precedes the .386 or .486 directive, USE16 is the default. To make USE32 the default, put .386 or .486 before .MODEL. You can override the USE32 default with the USE16 attribute, or vice versa.

Note Programs written for MS-DOS must not specify USE32. Mixing 16-bit and 32-bit segments in the same program is possible but usually applies only to systems programming.

Setting Segment Order with Class Type

The optional class type in the SEGMENT directive helps control segment ordering. Two segments with the same name are not combined if their class is different. The linker arranges segments so that all segments identified with a given class type are next to each other in the executable file. However, within a particular class, the linker arranges segments in the order encountered. The .ALPHA, .SEQ, or .DOSSEG directive determines this order in each .OBJ file. The most common method for specifying a class type is to place all code segments first in the executable file.

Controlling the Segment Order

The assembler normally positions segments in the object file in the order in which they appear in source code. The linker, in turn, processes object files in the order in which they appear on the command line. Within each object file, the linker outputs segments in the order they appear, subject to any group, class, and .DOSSEG requirements.

You can usually ignore segment ordering. However, it is important whenever you want certain segments to appear at the beginning or end of a program or when you make assumptions about which segments are next to each other in memory. For tiny model (.COM) programs, code segments must appear first in the executable file, because execution must start at the address 100h.

Segment Order Directives

You can control the order in which segments appear in the executable program with three directives. The default, .SEQ, arranges segments in the order in which you declare them.

The .ALPHA directive specifies alphabetical segment ordering within a module. .ALPHA is provided for compatibility with early versions of the IBM assembler. If you have trouble running code from older books on assembly language, try using .ALPHA.

The .DOSSEG directive specifies the MS-DOS segment-ordering convention. It places segments in the standard order required by Microsoft languages. Do not use .DOSSEG in a module to be called from another module.
The **.DOSSEG** directive orders segments as follows:

1. Code segments
2. Data segments, in this order:
   a. Segments not in class BSS or STACK
   b. Class BSS segments
   c. Class STACK segments

When you declare two or more segments to be in the same class, the linker automatically makes them contiguous. This rule overrides the segment-ordering directives. (For more about segment classes, see “Setting Segment Order with Class Type” in the previous section.)

**Linker Control**

Most of the segment-ordering techniques (class names, **.ALPHA**, and **.SEQ**) control the order in which the assembler outputs segments. Usually, you are more interested in the order in which segments appear in the executable file. The linker controls this order.

The linker processes object files in the order in which they appear on the command line. Within each module, it then outputs segments in the order given in the object file. If the first module defines segments DSEG and STACK and the second module defines CSEG, then CSEG is output last. If you want to place CSEG first, there are two ways to do so.

The simpler method is to use **.DOSSEG**. This directive is output as a special record to the object file linker, and it tells the linker to use the Microsoft segment-ordering convention. This convention overrides command-line order of object files, and it places all segments of class 'CODE' first. (See “Defining Segments with the SEGMENT Directive,” previous.)

The other method is to define all the segments as early as possible (in an include file, for example, or in the first module). These definitions can be “dummy segments”—that is, segments with no content. The linker observes the segment ordering given, then later combines the empty segments with segments in other modules that have the same name.
For example, you might include the following at the start of the first module of your program or in an include file:

```
_TEXT SEGMENT WORD PUBLIC 'CODE'
_TEXT ENDS
_DATA SEGMENT WORD PUBLIC 'DATA'
_DATA ENDS
_CONST SEGMENT WORD PUBLIC 'CONST'
_CONST ENDS
_STACK SEGMENT PARA STACK 'STACK'
_STACK ENDS
```

Later in the program, the order in which you write _TEXT, _DATA, or other segments does not matter because the ultimate order is controlled by the segment order defined in the include file.

### Setting the ASSUME Directive for Segment Registers

Many of the assembler instructions assume a default segment. For example, **JMP** assumes the segment associated with the CS register, **PUSH** and **POP** assume the segment associated with the SS register, and **MOV** instructions assume the segment associated with the DS register.

When the assembler needs to reference an address, it must know what segment contains the address. It finds this by using the default segment or group addresses assigned with the **ASSUME** directive. The syntax is:

```
ASSUME segregister : seglocation [, segregister : seglocation] 
ASSUME dataregister : qualifiedtype [, dataregister : qualifiedtype] 
ASSUME register : ERROR [, register : ERROR] 
ASSUME register : NOTHING [, register : NOTHING] 
ASSUME register : FLAT [, register : FLAT] 
```

The `seglocation` must be the name of the segment or group that is to be associated with `segregister`. Subsequent instructions that assume a default register for referencing labels or variables automatically assume that if the default segment is `segregister`, the label or variable is in the `seglocation`. MASM 6.1 automatically gives CS the address of the current code segment. Therefore, you do not need to include

```
ASSUME CS : MY_CODE
```

at the beginning of your program if you want the current segment associated with CS.
Note  Using the ASSUME directive to tell the assembler which segment to associate with a segment register is not the same as telling the processor. The ASSUME directive affects only assembly-time assumptions. You may need to use instructions to change run-time conditions. Initializing segment registers at run time is discussed in “Informing the Assembler About Segment Values,” Chapter 3.

The ASSUME directive can define a segment for each of the segment registers. The segregister can be CS, DS, ES, or SS (and FS and GS on the 80386/486). The seglocation must be one of the following:

- The name of a segment defined in the source file with the SEGMENT directive.
- The name of a group defined in the source file with the GROUP directive.
- The keyword NOTHING, ERROR, or FLAT.
- A SEG expression (see “Immediate Operands” in Chapter 3).
- A string equate (text macro) that evaluates to a segment or group name (but not a string equate that evaluates to a SEG expression).

It is legal to combine assumes to FLAT with assumes to specific segments. Combinations might be necessary in operating-system code that handles both 16- and 32-bit segments.

The keyword NOTHING cancels the current segment assumptions. For example, the statement ASSUME NOTHING cancels all register assumptions made by previous ASSUME statements.

Usually, a single ASSUME statement defines all four segment registers at the start of the source file. However, you can use the ASSUME directive at any point to change segment assumptions.

Using the ASSUME directive to change segment assumptions is often equivalent to changing assumptions with the segment-override operator (:). See “Direct Memory Operands” in Chapter 3. The segment-override operator is more convenient for one-time overrides. The ASSUME directive may be more convenient if previous assumptions must be overridden for a sequence of instructions.

However, in either case, your program must explicitly load a segment register with a segment address before accessing data within the segment. ASSUME only tells the assembler to assume that the register is correctly initialized; it does not by itself generate any code to load the register.
You can also prevent the use of a register with:

```
ASSUME SegRegister : ERROR
```

The assembler generates an `ASSUME CS: ERROR` when you use simplified directives to create data segments, effectively preventing instructions or code labels from appearing in a data segment.

For more information about `ASSUME`, refer to “Defining Register Types with `ASSUME`” in Chapter 3.

## Defining Segment Groups

A group is a collection of segments totalling not more than 64K in 16-bit mode. A program addresses a code or data item in the group relative to the beginning of the group.

A group lets you develop separate logical segments for different kinds of data and then combine these into one segment (a group) for all the data. Using a group can save you from having to continually reload segment registers to access different segments. As a result, the program uses fewer instructions and runs faster.

The most common example of a group is the specially named group for near data, DGROUP. In the Microsoft segment model, several segments (\_DATA, \_BSS, CONST, and STACK) are combined into a single group called DGROUP. Microsoft high-level languages place all near data segments in this group. (By default, the stack is placed here, too.) The `.MODEL` directive automatically defines DGROUP. The DS register normally points to the beginning of the group, giving you relatively fast access to all data in DGROUP.

The syntax of the group directive is:

```
name GROUP segment [,, segment]...
```

The `name` labels the group. It can refer to a group that was previously defined. This feature lets you add segments to a group one at a time. For example, if `MYGROUP` was previously defined to include ASEG and BSEG, then the statement

```
MYGROUP GROUP CSEG
```

is perfectly legal. It simply adds CSEG to the group `MYGROUP`; ASEG and BSEG are not removed.

Each `segment` can be any valid segment name (including a segment defined later in source code), with one restriction: a segment cannot belong to more than one group.
The **GROUP** directive does not affect the order in which segments of a group are loaded. You can place any number of 16-bit segments in a group as long as the total size does not exceed 65,536 bytes. If the processor is in 32-bit mode, the maximum size is 4 gigabytes. You need to make sure that non-grouped segments do not get placed between grouped segments in such a way that the size of the group exceeds 64K or 4 gigabytes. Neither can you place a 16-bit and a 32-bit segment in the same group.
CHAPTER 3

Using Addresses and Pointers

MASM applications running in real mode require segmented addresses to access code and data. The address of the code or data in a segment is relative to a segment address in a segment register. You can also use pointers to access data in assembly language programs. (A pointer is a variable that contains an address as its value.)

The first section of this chapter describes how to initialize default segment registers to access near and far addresses. The next section describes how to access code and data. It also describes related operators, syntax, and displacements. The discussion of memory operands lays the foundation for the third section, which describes the stack.

The fourth section of this chapter explains how to use the **TYPEDEF** directive to declare pointers and the **ASSUME** directive to give the assembler information about registers containing pointers. This section also shows you how to do typical pointer operations and how to write code that works for pointer variables in any memory model.

Programming Segmented Addresses

Before you use segmented addresses in your programs, you need to initialize the segment registers. The initialization process depends on the registers used and on your choice of simplified segment directives or full segment definitions. The simplified segment directives (introduced in Chapter 2) handle most of the initialization process for you. This section explains how to inform the assembler and the processor of segment addresses, and how to access the near and far code and data in those segments.

Initializing Default Segment Registers

The segmented architecture of the 8086-family of processors does not require that you specify two addresses every time you access memory. As explained in Chapter 2, “Organizing Segments,” the 8086 family of processors uses a system
of default segment registers to simplify access to the most commonly used data and code.

The segment registers DS, SS, and CS are normally initialized to default segments at the beginning of a program. If you write the main module in a high-level language, the compiler initializes the segment registers. If you write the main module in assembly language, you must initialize the segment registers yourself. Follow these steps to initialize segments:

1. Tell the assembler which segment is associated with a register. The assembler must know the default segments at assembly time.
2. Tell the processor which segment is associated with a register by writing the necessary code to load the correct segment value into the segment register on the processor.

These steps are discussed separately in the following sections.

**Informing the Assembler About Segment Values**

The first step in initializing segments is to tell the assembler which segment to associate with a register. You do this with the **ASSUME** directive. If you use simplified segment directives, the assembler automatically generates the appropriate **ASSUME** statements. If you use full segment definitions, you must code the **ASSUME** statements for registers other than CS yourself. (**ASSUME** can also be used on general-purpose registers, as explained in “Defining Register Types with **ASSUME**” later in this chapter.)

The **.STARTUP** directive generates startup code that sets DS equal to SS (unless you specify **FARSTACK**), allowing default data to be accessed through either SS or DS. This can improve efficiency in the code generated by compilers. The “DS equals SS” convention may not work with certain applications, such as memory-resident programs in MS-DOS and Windows dynamic-link libraries (see Chapter 10). The code generated for **.STARTUP** is shown in “Starting and Ending Code with **.STARTUP** and **.EXIT**” in Chapter 2. You can use similar code to set DS equal to SS in programs using full segment definitions.

Here is an example of **ASSUME** using full segment definitions:

```assembly
ASSUME cs: _TEXT, ds: DGROUP, ss: DGROUP
```

This example is equivalent to the **ASSUME** statement generated with simplified segment directives in small model with **NEARSTACK**. Note that DS and SS are part of the same segment group. It is also possible to have different segments for data and code, and to use **ASSUME** to set ES, as shown here:
ASSUME cs:MYCODE, ds:MYDATA, ss:MYSTACK, es:OTHER

Correct use of the ASSUME statement can help find addressing errors. With .CODE, the assembler assumes CS is the current segment. When you use the simplified segment directives .DATA, .DATA?, .CONST, .FAR DATA, or .FAR DATA?, the assembler automatically assumes CS is the ERROR segment. This prevents instructions from appearing in these segments. If you use full segment definitions, you can accomplish the same by placing ASSUME CS: ERROR in a data segment.

With simple or full segments, you can cancel the control of an ASSUME statement by assuming NOTHING. You can cancel the previous assumption for ES with the following statement:

ASSUME es:NOTHING

Prior to the .MODEL statement (or in its absence), the assembler sets the ASSUME statement for DS, ES, and SS to the current segment.

Informing the Processor About Segment Values

The second and final step in initializing segments is to inform the processor of segment values at run time. How segment values are initialized at run time differs for each segment register and depends on the operating system and on your use of simplified segment directives or full segment definitions.

Specifying a Starting Address

A program’s starting address determines where execution begins. After the operating system loads a program, it simply jumps to the starting address, giving processor control to the program. The true starting address is known only to the loader; the linker determines only the offset of the address within an undetermined code segment. That’s why a normal application is often referred to as “relocatable code,” because it runs regardless of where the loader places it in memory.

The offset of the starting address depends on the program type. Programs with an .EXE extension contain a header from which the loader reads the offset and combines it with a segment to form the starting address. Programs with a .COM extension (tiny model) have no such header, so by convention the loader jumps to the first byte of the program.

In either case, the .STARTUP directive identifies where execution begins, provided you use simplified segment directives. For an .EXE program, place .STARTUP immediately before the instruction where you want execution to start. In a .COM program, place .STARTUP before the first assembly instruction in your source code.
If you use full segment directives or prefer not to use .STARTUP, you must identify the starting instruction in two steps:

1. Label the starting instruction.
2. Provide the same label in the END directive.

These steps tell the linker where execution begins in the program. The following example illustrates the two steps for a tiny model program:

```
_TEXT SEGMENT WORD PUBLIC 'CODE'
ORG 100h ; Use this declaration for .COM files only
start:  .               ; First instruction here
      .
_TEXT ENDS
END start   ; Name of starting label
```

Notice the ORG statement in this example. This statement is mandatory in a tiny model program without the .STARTUP directive. It places the first instruction at offset 100h in the code segment to create space for a 256-byte (100h) data area called the Program Segment Prefix (PSP). The operating system takes care of initializing the PSP, so you need only make sure the area exists. (For a description of what data resides in the PSP, refer to the “Tables” chapter in the Reference.)

**Initializing DS**

The DS register is automatically initialized to the correct value (DGROUP) if you use .STARTUP or if you are writing a program for Windows. If you do not use .STARTUP with MS-DOS, you must initialize DS using the following instructions:

```
mov ax, DGROUP
mov ds, ax
```

The initialization requires two instructions because the segment name is a constant and the assembler does not allow a constant to be loaded directly to a segment register. The previous example loads DGROUP, but you can load any valid segment or group.

**Initializing SS and SP**

The SS and SP registers are initialized automatically if you use the .STACK directive with simplified segments or if you define a segment that has the STACK combine type with full segment definitions. Using the STACK directive initializes SS to the stack segment. If you want SS to be equal to DS, use .STARTUP or its equivalent. (See “Combining Segments,” page 45.) For an .EXE file, the stack address is encoded into the executable header and resolved.
at load time. For a .COM file, the loader sets SS equal to CS and initializes SP to 0FFFEh.

If your program does not access far data, you do not need to initialize the ES register. If you choose to initialize, use the same technique as for the DS register. You can initialize SS to a far stack in the same way.

Near and Far Addresses

Addresses that have an implied segment name or segment registers associated with them are called “near addresses.” Addresses that have an explicit segment associated with them are called “far addresses.” The assembler handles near and far code automatically, as described in the following sections. You must specify how to handle far data.

The Microsoft segment model puts all near data and the stack in a group called DGROUP. Near code is put in a segment called _TEXT. Each module’s far code or far data is placed in a separate segment. This convention is described in “Controlling the Segment Order” in Chapter 2.

The assembler cannot determine the address for some program components; these are said to be relocatable. The assembler generates a fixup record and the linker provides the address once it has determined the location of all segments. Usually a relocatable operand references a label, but there are exceptions. Examples in the next two sections include information about relocating near and far data.

Near Code

Control transfers within near code do not require changes to segment registers. The processor automatically handles changes to the offset in the IP register when control-flow instructions such as JMP, CALL, and RET are used. The statement

```assembly
call nearproc ; Change code offset
```

changes the IP register to the new address but leaves the segment unchanged. When the procedure returns, the processor resets IP to the offset of the next instruction after the CALL instruction.

Far Code

The processor automatically handles segment register changes when dealing with far code. The statement

```assembly
call farproc ; Change code segment and offset
```

automatically moves the segment and offset of the far proc procedure to the CS and IP registers. When the procedure returns, the processor sets CS to the
original code segment and sets IP to the offset of the next instruction after the call.

**Near Data**

A program can access near data directly, because a segment register already holds the correct segment for the data item. The term “near data” is often used to refer to the data in the DGROUP group.

After the first initialization of the DS and SS registers, these registers normally point into DGROUP. If you modify the contents of either of these registers during the execution of the program, you must reload the register with DGROUP’s address before referencing any DGROUP data.

The processor assumes all memory references are relative to the segment in the DS register, with the exception of references using BP or SP. The processor associates these registers with the SS register. (You can override these assumptions with the segment override operator, described in “Direct Memory Operands,” on page 62.)

The following lines illustrate how the processor accesses either the DS or SS segments, depending on whether the pointer operand contains BP or SP. Note the distinction loses significance when DS and SS are equal.

```
near var WORD    0

mov     ax, near var ; Reads from DS:
mov     di, [bx]    ; Reads from DS:
mov     [di], cx    ; Writes to DS:
mov     [bp+6], ax  ; Writes to SS:
mov     bx, [bp]    ; Reads from SS:
```

**Far Data**

To read or modify a far address, a segment register must point to the segment of the data. This requires two steps. First load the segment (normally either ES or DS) with the correct value, and then (optionally) set an assume of the segment register to the segment of the address.

**Note** Flat model does not require far addresses. By default, all addressing is relative to the initial values of the segment registers. Therefore, this section on far addressing does not apply to flat model programs.

One method commonly used to access far data is to initialize the ES segment register. This example shows two ways to do this:
; First method
mov    ax, SEG farvar ; Load segment of the
mov    es, ax          ;   far address into ES
mov    ax, es:farvar  ; Provide an explicit segment
                    ;   override on the addressing
; Second method
    mov    ax,SEG farvar2 ; Load the segment of the
    mov    es,ax          ;   far address into ES
    assume ES:SEG farvar2 ; Tell the assembler that ES points
                        ;   to the segment containing farvar2
    mov    ax,farvar2     ; The assembler provides the ES
                        ; override since it knows that
                        ; the label is addressable

After loading the segment of the address into the ES segment register, you can
explicitly override the segment register so that the addressing is correct (method
1) or allow the assembler to insert the override for you (method 2). The
assembler uses **ASSUME** statements to determine which segment register can
be used to address a segment of memory. To use the segment override operator,
the left operand must be a segment register, not a segment name. (For more
information on segment overrides, see “Direct Memory Operands” on page 62.)

If an instruction needs a segment override, the resulting code is slightly larger
and slower, since the override must be encoded into the instruction. However,
the resulting code may still be smaller than the code for multiple loads of the
default segment register for the instruction.

The DS, SS, FS, and GS segment registers (FS and GS are available only on the
80386/486 processors) may also be used for addressing through other segments.

If a program uses ES to access far data, it need not restore ES when finished
(unless the program uses flat model). However, some compilers require that you
restore ES before returning to a module written in a high-level language.

To access far data, first set DS to the far segment and then restore the original
DS when finished. Use the **ASSUME** directive to let the assembler know that
DS no longer points to the default data segment, as shown here:

    push    ds               ; Save original segment
    mov    ax,SEG fararray ; Move segment into data register
    mov    ds,ax             ; Initialize segment register
    assume ds:SEG fararray ; Tell assembler where data is
    mov    ax,fararray[0]   ; Set DX:AX = dword variable
    mov    dx,fararray[2]   ; fararray
    .
    .
    pop     ds               ; Restore segment
    assume ds:@DATA          ; and default assumption
“Direct Memory Operands,” on page 62, describes an alternative method for accessing far data. The technique of resetting DS as shown in the previous example is best for a lengthy series of far data references. The segment override method described in “Direct Memory Operands” serves best when accessing only one or two far variables.

If your program changes DS to access far data, it should restore DS when finished. This allows procedures to assume that DS is the segment for near data. Many compilers, including Microsoft compilers, use this convention.

Operands

With few exceptions, assembly language instructions work on sources of data called operands. In a listing of assembly code (such as the examples in this book), operands appear in the operand field immediately to the right of the instructions.

This section describes the four kinds of instruction operands: register, immediate, direct memory, and indirect memory. Some instructions, such as POPF and STI, have implied operands which do not appear in the operand field. Otherwise, an implied operand is just as real as one stated explicitly.

Certain other instructions such as NOP and WAIT deserve special mention. These instructions affect only processor control and do not require an operand.

The following four types of operands are described in the rest of this section:

<table>
<thead>
<tr>
<th>Operand Type</th>
<th>Addressing Mode</th>
</tr>
</thead>
<tbody>
<tr>
<td>Register</td>
<td>An 8-bit or 16-bit register on the 8086–80486; can also be 32-bit on the 80386/486.</td>
</tr>
<tr>
<td>Immediate</td>
<td>A constant value contained in the instruction itself.</td>
</tr>
<tr>
<td>Direct memory</td>
<td>A fixed location in memory.</td>
</tr>
<tr>
<td>Indirect memory</td>
<td>A memory location determined at run time by using the address stored in one or two registers.</td>
</tr>
</tbody>
</table>

Instructions that take two or more operands always work right to left. The right operand is the source operand. It specifies data that will be read, but not changed, in the operation. The left operand is the destination operand. It specifies the data that will be acted on and possibly changed by the instruction.
Register Operands

Register operands refer to data stored in registers. The following examples show typical register operands:

```
mov     bx, 10          ; Load constant to BX
add     ax, bx          ; Add BX to AX
jmp     di              ; Jump to the address in DI
```

An offset stored in a base or index register often serves as a pointer into memory. You can store an offset in one of the base or index registers, then use the register as an indirect memory operand. (See “Indirect Memory Operands,” following.) For example:

```
mov     [bx], dl ; Store DL in indirect memory operand
inc     bx       ; Increment register operand
mov     [bx], dl ; Store DL in new indirect memory operand
```

This example moves the value in DL to 2 consecutive bytes of a memory location pointed to by BX. Any instruction that changes the register value also changes the data item pointed to by the register.

Immediate Operands

An immediate operand is a constant or the result of a constant expression. The assembler encodes immediate values into the instruction at assembly time. Here are some typical examples showing immediate operands:

```
mov     cx, 20          ; Load constant to register
add     var, 1Fh        ; Add hex constant to variable
sub     bx, 25 * 80     ; Subtract constant expression
```

Immediate data is never permitted in the destination operand. If the source operand is immediate, the destination operand must be either a register or direct memory to provide a place to store the result of the operation.

Immediate expressions often involve the useful OFFSET and SEG operators, described in the following paragraphs.

The OFFSET Operator

An address constant is a special type of immediate operand that consists of an offset or segment value. The OFFSET operator returns the offset of a memory location, as shown here:

```
mov     bx, OFFSET var ; Load offset address
```

For information on differences between MASM 5.1 behavior and MASM 6.1 behavior related to OFFSET, see Appendix A.
Since data in different modules may belong to a single segment, the assembler cannot know for each module the true offsets within a segment. Thus, the offset for var, although an immediate value, is not determined until link time.

**The SEG Operator**

The SEG operator returns the segment of a memory location:

```assembly
mov ax, SEG farvar ; Load segment address
mov es, ax
```

The actual value of a particular segment is not known until the program is loaded into memory. For .EXE programs, the linker makes a list in the program’s header of all locations in which the SEG operator appears. The loader reads this list and fills in the required segment address at each location. Since .COM programs have no header, the assembler does not allow relocatable segment expressions in tiny model programs.

The SEG operator returns a variable’s “frame” if it appears in the instruction. The frame is the value of the segment, group, or segment override of a nonexternal variable. For example, the instruction

```assembly
mov ax, SEG DGROUP:var
```

places in AX the value of DGROUP, where var is located. If you do not include a frame, SEG returns the value of the variable’s group if one exists. If the variable is not defined in a group, SEG returns the variable’s segment address.

This behavior can be changed with the /Zm command-line option or with the OPTION OFFSET:SEGMENT statement. (See Appendix A, “Differences between MASM 6.1 and 5.1.”) “Using the OPTION Directive” in Chapter 1 introduces the OPTION directive.

**Direct Memory Operands**

A direct memory operand specifies the data at a given address. The instruction acts on the contents of the address, not the address itself. Except when size is implied by another operand, you must specify the size of a direct memory operand so the instruction accesses the correct amount of memory. The following example shows how to explicitly specify data size with the BYTE directive:
Any location in memory can be a direct memory operand as long as a size is specified (or implied) and the location is fixed. The data at the address can change, but the address cannot. By default, instructions that use direct memory addressing use the DS register. You can create an expression that points to a memory location using any of the following operators:

<table>
<thead>
<tr>
<th>Operator Name</th>
<th>Symbol</th>
</tr>
</thead>
<tbody>
<tr>
<td>Plus</td>
<td>+</td>
</tr>
<tr>
<td>Minus</td>
<td>–</td>
</tr>
<tr>
<td>Index</td>
<td>[ ]</td>
</tr>
<tr>
<td>Structure member</td>
<td>.</td>
</tr>
<tr>
<td>Segment override</td>
<td>:</td>
</tr>
</tbody>
</table>

These operators are discussed in more detail in the following section.

**Plus, Minus, and Index**

The plus and index operators perform in exactly the same way when applied to direct memory operands. For example, both the following statements move the second word value from an array into the AX register:

- `mov ax, array[2]`
- `mov ax, array+2`

The index operator can contain any direct memory operand. The following statements are equivalent:

- `mov ax, var`
- `mov ax, [var]`

Some programmers prefer to enclose the operand in brackets to show that the contents, not the address, are used.
The minus operator behaves as you would expect. Both the following instructions retrieve the value located at the word preceding array:

```
mov     ax, array[-2]
mov     ax, array-2
```

**Structure Field**

The structure operator (.) references a particular element of a structure or “field,” to use C terminology:

```
mov     bx, structvar.field1
```

The address of the structure operand is the sum of the offsets of structvar and field1. For more information about structures, see “Structures and Unions” in Chapter 5.

**Segment Override**

The segment override operator (:) specifies a segment portion of the address that is different from the default segment. When used with instructions, this operator can apply to segment registers or segment names:

```
mov     ax, es:farvar           ; Use segment override
```

The assembler will not generate a segment override if the default segment is explicitly provided. Thus, the following two statements assemble in exactly the same way:

```
mov     [bx], ax
mov     ds:[bx], ax
```

A segment name override or the segment override operator identifies the operand as an address expression.

```
mov     WORD PTR FARSEG 0, ax   ; Segment name override
mov     WORD PTR es:100h, ax    ; Legal and equivalent
mov     WORD PTR es:[100h], ax  ; expressions
; mov     WORD PTR [100h], ax    ; Illegal, not an address
```

As the example shows, a constant expression cannot be an address expression unless it has a segment override.

**Indirect Memory Operands**

Like direct memory operands, indirect memory operands specify the contents of a given address. However, the processor calculates the address at run time by referring to the contents of registers. Since values in the registers can change at run time, indirect memory operands provide dynamic access to memory.
Indirect memory operands make possible run-time operations such as pointer indirection and dynamic indexing of array elements, including indexing of multidimensional arrays.

Strict rules govern which registers you can use for indirect memory operands under 16-bit versions of the 8086-based processors. The rules change significantly for 32-bit processors starting with the 80386. However, the new rules apply only to code that does not need to be compatible with earlier processors.

This section covers features of indirect operands in either mode. The specific 16-bit rules and 32-bit rules are then explained separately.

**Indirect Operands with 16- and 32-Bit Registers**

Some rules and options for indirect memory operands always apply, regardless of the size of the register. For example, you must always specify the register and operand size for indirect memory operands. But you can use various syntaxes to indicate an indirect memory operand. This section describes the rules that apply to both 16-bit and 32-bit register modes.

**Specifying Indirect Memory Operands**

The index operator specifies the register or registers for indirect operands. The processor uses the data pointed to by the register. For example, the following instruction moves into AX the word value at the address in DS:BX.

```assembly
mov     ax, WORD PTR [bx]
```

When you specify more than one register, the processor adds the contents of the two addresses together to determine the effective address (the address of the data to operate on):

```assembly
mov     ax, [bx+si]
```

**Specifying Displacements**

You can specify an address displacement, which is a constant value added to the effective address. A direct memory specifier is the most common displacement:

```assembly
mov     ax, table[si]
```

In this relocatable expression, the displacement `table[si]` is the base address of an array; SI holds an index to an array element. The SI value is calculated at run time, often in a loop. The element loaded into AX depends on the value of SI at the time the instruction executes.
Each displacement can be an address or numeric constant. If there is more than one displacement, the assembler totals them at assembly time and encodes the total displacement. For example, in the statement

```assembly
table WORD 100 DUP (0)
.
.
.
mov ax, table[ bx ][ di ] + 6
```

both `table` and 6 are displacements. The assembler adds the value of 6 to `table` to get the total displacement. However, the statement

```assembly
mov ax, mem1[ si ] + mem2
```

is not legal, because it attempts to use a single command to join the contents of two different addresses.

**Specifying Operand Size**

You must give the size of an indirect memory operand in one of three ways:

- By the variable’s declared size
- With the `PTR` operator
- Implied by the size of the other operand

The following lines illustrate all three methods. Assume the size of the `table` array is `WORD`, as declared earlier.

```assembly
mov table[ bx ], 0 ; 2 bytes - from size of table
mov BYTE PTR table, 0 ; 1 byte - specified by BYTE
mov ax, [ bx ] ; 2 bytes - implied by AX
```

**Syntax Options**

The assembler allows a variety of syntaxes for indirect memory operands. However, all registers must be inside brackets. You can enclose each register in its own pair of brackets, or you can place the registers in the same pair of brackets separated by a plus operator (+). All the following variations are legal and assemble the same way:

```assembly
mov ax, table[ bx ][ di ]
mov ax, table[ di ][ bx ]
mov ax, table[ bx+di ]
mov ax, [ table+bx+di ]
mov ax, [ bx ][ di ] + table
```

All of these statements move the value in `table` indexed by BX+DI into AX.
Scaling Indexes
The value of index registers pointing into arrays must often be adjusted for zero-based arrays and scaled according to the size of the array items. For a word array, the item number must be multiplied by two (shifted left by one place). When using 16-bit registers, you must scale with separate instructions, as shown here:

```
mov    bx, 5 ; Get sixth element (adjust for 0)
shl    bx, 1 ; Scale by two (word size)
inc    wtable[bx] ; Increment sixth element in table
```

When using 32-bit registers on the 80386/486 processor, you can include scaling in the operand, as described in “Indirect Memory Operands with 32-Bit Registers,” following.

Accessing Structure Elements
The structure member operator can be used in indirect memory operands to access structure elements. In this example, the structure member operator loads the `year` field of the fourth element of the `students` array into AL:

```
STUDENT STRUCT
    grade WORD  ?
    name  BYTE  20 DUP (?)
    year  BYTE  ?
STUDENT ENDS

students        STUDENT  < >
.
.
    mov     bx, OFFSET students    ; Point to array of students
    mov     ax, 4                   ; Get fourth element
    mov     di, SIZE STUDENT        ; Get size of STUDENT
    mul     di                      ; Multiply size times
    mov     ax, di                  ; Elements to point DI
    mov     al, (STUDENT PTR[bx+di]).year
```

For more information on MASM structures, see “Structures and Unions” in Chapter 5.

Indirect Memory Operands with 16-Bit Registers
For 8086-based computers and MS-DOS, you must follow the strict indexing rules established for the 8086 processor. Only four registers are allowed—BP, BX, SI, and DI—those only in certain combinations.
BP and BX are base registers. SI and DI are index registers. You can use either a base or an index register by itself. But if you combine two registers, one must be a base and one an index. Here are legal and illegal forms:

\[
\begin{align*}
\text{mov} & \ ax, [bx+di] \quad ; \text{Legal} \\
\text{mov} & \ ax, [bx+si] \quad ; \text{Legal} \\
\text{mov} & \ ax, [bp+di] \quad ; \text{Legal} \\
\text{mov} & \ ax, [bp+si] \quad ; \text{Legal} \\
\text{mov} & \ ax, [bx+bp] \quad ; \text{Illegal - two base registers} \\
\text{mov} & \ ax, [di+si] \quad ; \text{Illegal - two index registers}
\end{align*}
\]

Table 3.1 shows the register modes in which you can specify indirect memory operands.

**Table 3.1  Indirect Addressing with 16-Bit Registers**

</tbody>
</table>

Different combinations of registers and displacements have different timings, as shown in Reference.

**Indirect Memory Operands with 32-Bit Registers**

You can write instructions for the 80386/486 processor using either 16-bit or 32-bit segments. Indirect memory operands are different in each case.

In 16-bit real mode, the 80386/486 operates the same way as earlier 8086-based processors, with one difference: you can use 32-bit registers. If the 80386/486 processor is enabled (with the .386 or .486 directive), 32-bit general-purpose registers are available with either 16-bit or 32-bit segments. Thirty-two–bit
registers eliminate many of the limitations of 16-bit indirect memory operands. You can use 80386/486 features to make your MS-DOS programs run faster and more efficiently if you are willing to sacrifice compatibility with earlier processors.

In 32-bit mode, an offset address can be up to 4 gigabytes. (Segments are still represented in 16 bits.) This effectively eliminates size restrictions on each segment, since few programs need 4 gigabytes of memory. Windows NT uses 32-bit mode and flat model, which spans all segments. XENIX 386 uses 32-bit mode with multiple segments.

80386/486 Enhancements

On the 80386/486, the processor allows you to use any general-purpose 32-bit register as a base or index register, except ESP, which can be a base but not an index. However, you cannot combine 16-bit and 32-bit registers. Several examples are shown here:

```
add     edx, [eax]              ; Add double
mov     dl, [esp+10]            ; Copy byte from stack
dec     WORD PTR [edx][eax]     ; Decrement word
cmp     ax, array[ebx][ecx]     ; Compare word from array
jmp     FWORD PTR table[ecx]    ; Jump into pointer table
```

Scaling Factors

With 80386/486 registers, the index register can have a scaling factor of 1, 2, 4, or 8. Any register except ESP can be the index register and can have a scaling factor. To specify the scaling factor, use the multiplication operator (*) adjacent to the register.

You can use scaling to index into arrays with different sizes of elements. For example, the scaling factor is 1 for byte arrays (no scaling needed), 2 for word arrays, 4 for doubleword arrays, and 8 for quadword arrays. There is no performance penalty for using a scaling factor. Scaling is illustrated in the following examples:

```
mov    eax, darray[edx*4]     ; Load double of double array
mov    eax, [esi*8][edi]      ; Load double of quad array
mov    ax, wtbl[ecx+2][edx*2] ; Load word of word array
```

Scaling is also necessary on earlier processors, but it must be done with separate instructions before the indirect memory operand is used, as described in “Indirect Memory Operands with 16-Bit Registers,” previous.

The default segment register is SS if the base register is EBP or ESP. However, if EBP is scaled, the processor treats it as an index register with a value relative to DS, not SS.
All other base registers are relative to DS. If two registers are used, only one can have a scaling factor. The register with the scaling factor is defined as the index register. The other register is defined as the base. If scaling is not used, the first register is the base. If only one register is used, it is considered the base for deciding the default segment unless it is scaled. The following examples illustrate how to determine the base register:

- `mov eax, [edx][ebp*4]` ; EDX base (not scaled - seg DS)
- `mov eax, [edx*1][ebp]` ; EBP base (not scaled - seg SS)
- `mov eax, [edx][ebp]` ; EDX base (first - seg DS)
- `mov eax, [ebp][edx]` ; EBP base (first - seg SS)
- `mov eax, [ebp]` ; EBP base (only - seg SS)
- `mov eax, [ebp*2]` ; EBP*2 index (seg DS)

**Mixing 16-Bit and 32-Bit Registers**

Assembly statements can mix 16-bit and 32-bit registers. For example, the following statement is legal for 16-bit and 32-bit segments:

- `mov eax, [bx]`

This statement moves the 32-bit value pointed to by BX into the EAX register. Although BX is a 16-bit pointer, it can still point into a 32-bit segment.

However, the following statement is never legal, since you cannot use the CX register as a 16-bit pointer:

- `; mov eax, [cx] ; illegal`

Operands that mix 16-bit and 32-bit registers are also illegal:

- `; mov eax, [ebx+si] ; illegal`

The following statement is legal in either 16-bit or 32-bit mode:

- `mov bx, [eax]`

This statement moves the 16-bit value pointed to by EAX into the BX register. This works in 32-bit mode. However, in 16-bit mode, moving a 32-bit pointer into a 16-bit segment is illegal. If EAX contains a 16-bit value (the top half of the 32-bit register is 0), the statement works. However, if the top half of the EAX register is not 0, the operand points into a part of the segment that doesn’t exist, generating an error. If you use 32-bit registers as indexes in 16-bit mode, you must make sure that the index registers contain valid 16-bit addresses.

**The Program Stack**

The preceding discussion on memory operands lays the groundwork for understanding the important data area known as the “stack.”
A stack is an area of memory for storing data temporarily. Unlike other segments that store data starting from low memory, the stack stores data starting from high memory. Data is always pushed onto, or “popped” from the top of the stack.

The stack gets its name from its similarity to the spring-loaded plate holders in cafeterias. You add and remove plates from only the top of the stack. To retrieve the third plate, you must remove—that is, “pop”—the first two plates. Stacks are often referred to as LIFO buffers, from their last-in-first-out operation.

A stack is an essential part of any nontrivial program. A program continually uses its stack to temporarily store return addresses, procedure arguments, memory data, flags, or registers.

The SP register serves as an indirect memory operand to the top of the stack. At first, the stack is an uninitialized segment of a finite size. As your program adds data to the stack, the stack grows downward from high memory to low memory. When you remove items from the stack, it shrinks upward from low to high memory.

**Saving Operands on the Stack**

The **PUSH** instruction stores a 2-byte operand on the stack. The **POP** instruction retrieves the most recent pushed value. When a value is pushed onto the stack, the assembler decreases the SP (Stack Pointer) register by 2. On 8086-based processors, the SP register always points to the top of the stack. The **PUSH** and **POP** instructions use the SP register to keep track of the current position.

When a value is popped off the stack, the assembler increases the SP register by 2. Since the stack always contains word values, the SP register changes in multiples of two. When a **PUSH** or **POP** instruction executes in a 32-bit code segment (one with **USE32** use type), the assembler transfers a 4-byte value, and ESP changes in multiples of four.

**Note** The 8086 and 8088 processors differ from later Intel processors in how they push and pop the SP register. If you give the statement **push sp** with the 8086 or 8088, the word pushed is the word in SP after the push operation.
Figure 3.1 illustrates how pushes and pops change the SP register.

![Diagram of stack status before and after pushes and pops]

**Figure 3.1  Stack Status Before and After Pushes and Pops**

On the 8086, **PUSH** and **POP** take only registers or memory expressions as their operands. The other processors allow an immediate value to be an operand for **PUSH**. For example, the following statement is legal on the 80186–80486 processors:

```
push     7        ; 3 clocks on 80286
```

That statement is faster than these equivalent statements, which are required on the 8088 or 8086:

```
mov     ax, 7           ; 2 clocks plus
push    ax              ; 3 clocks on 80286
```

Words are popped off the stack in reverse order: the last item pushed is the first popped. To return the stack to its original status, you do the same number of
pops as pushes. You can subtract the correct number of words from the SP register if you want to restore the stack without using the values on it.

To reference operands on the stack, remember that the values pointed to by the BP (Base Pointer) and SP registers are relative to the SS (Stack Segment) register. The BP register is often used to point to the base of a frame of reference (a stack frame) within the stack. This example shows how you can access values on the stack using indirect memory operands with BP as the base register.

```assembly
push    bp              ; Save current value of BP
mov     bp, sp          ; Set stack frame
push    ax              ; Push first;  SP = BP - 2
push    bx              ; Push second; SP = BP - 4
push    cx              ; Push third; SP = BP - 6
.
.
mov     ax, [bp-6]      ; Put third word in AX
mov     bx, [bp-4]      ; Put second word in BX
mov     cx, [bp-2]      ; Put first word in CX
.
.
add     sp, 6           ; Restore stack pointer
; (two bytes per push)
pop     bp              ; Restore BP
```

If you often use these stack values in your program, you may want to give them labels. For example, you can use `TEXTEQU` to create a label such as `count <[bp-6]>`. Now you can replace the `mov ax, [bp-6]` statement in the previous example with `mov ax, count`. For more information about the `TEXTEQU` directive, see “Text Macros” in Chapter 9.

### Saving Flags on the Stack

Your program can push and pop flags onto the stack with the `PUSHF` and `POPF` instructions. These instructions save and then restore the status of the flags. You can also use them within a procedure to save and restore the flag status of the caller. The 32-bit versions of these instructions are `PUSHFD` and `POPFD`.

This example saves the flags register before calling the `systask` procedure:

```assembly
pushf
call    systask
popf
```
If you do not need to store the entire flags register, you can use the `LAHF` instruction to manually load and store the status of the lower byte of the flag register in the AH register. `SAHF` restores the value.

**Saving Registers on the Stack (80186–80486 Only)**

Starting with the 80186 processor, the `PUSHA` and `POPA` instructions push or pop all the general-purpose registers with only one instruction. These instructions save the status of all registers before a procedure call and restore them after the return. Using `PUSHA` and `POPA` is significantly faster and takes fewer bytes of code than pushing and popping each register individually.

The processor pushes the registers in the following order: AX, CX, DX, BX, SP, BP, SI, and DI. The SP word pushed is the value before the first register is pushed.

The processor pops the registers in the opposite order. The 32-bit versions of these instructions are `PUSHAD` and `POPAD`.

**Accessing Data with Pointers and Addresses**

A pointer is simply a variable that contains an address of some other variable. The address in the pointer “points” to the other object. Pointers are useful when transferring a large data object (such as an array) to a procedure. The caller places only the pointer on the stack, which the called procedure uses to locate the array. This eliminates the impractical step of having to pass the entire array back and forth through the stack.

There is a difference between a far address and a far pointer. A “far address” is the address of a variable located in a far data segment. A “far pointer” is a variable that contains the segment address and offset of some other data. Like any other variable, a pointer can be located in either the default (near) data segment or in a far segment.

Previous versions of MASM allow pointer variables but provide little support for them. In previous versions, any address loaded into a variable can be considered a pointer, as in the following statements:

```plaintext
Var     BYTE    0               ; Variable
npVar   WORD    Var             ; Near pointer to variable
fpVar   DWORD   Var             ; Far pointer to variable
```

If a variable is initialized with the name of another variable, the initialized variable is a pointer, as shown in this example. However, in previous versions of MASM, the CodeView debugger recognizes `npVar` and `fpVar` as word and doubleword variables. CodeView does not treat them as pointers, nor does it recognize the type of data they point to (bytes, in the example).
The **TYPEDEF** directive and enhanced capabilities of **ASSUME** (introduced in MASM 6.0) make it easier to manage pointers in registers and variables. The rest of this chapter describes these directives and how they apply to basic pointer operations.

### Defining Pointer Types with **TYPEDEF**

The **TYPEDEF** directive can define types for pointer variables. A type so defined is considered the same as the intrinsic types provided by the assembler and can be used in the same contexts. When used to define pointers, the syntax for **TYPEDEF** is:

```
typename TYPEDEF [[distance]] PTR qualifiedtype
```

The *typename* is the name assigned to the new type. The *distance* can be **NEAR**, **FAR**, or any distance modifier. The *qualifiedtype* can be any previously intrinsic or defined MASM type, or a type previously defined with **TYPEDEF**. (For a full definition of *qualifiedtype*, see “Data Types” in Chapter 1.)

Here are some examples of user-defined types:

```assembly
PBYTE  TYPEDEF      PTR BYTE   ; Pointer to bytes
NPBYTE TYPEDEF NEAR PTR BYTE   ; Near pointer to bytes
FPBYTE TYPEDEF FAR  PTR BYTE   ; Far pointer to bytes
PWORD  TYPEDEF      PTR WORD   ; Pointer to words
NPWORD TYPEDEF NEAR PTR WORD   ; Near pointer to words
FPWORD TYPEDEF FAR  PTR WORD   ; Far pointer to words
PPBYTE TYPEDEF      PTR PBYTE  ; Pointer to pointer to bytes
                    ; (in C, an array of strings)
PVOID  TYPEDEF      PTR        ; Pointer to any type of data
PERSON STRUCT                  ; Structure type
    name  BYTE    20 DUP (?)
    num   WORD    ?
PERSON ENDS
PPPERSON TYPEDEF PTR PERSON ; Pointer to structure type
```

The distance of a pointer can be set specifically or determined automatically by the memory model (set by `.MODEL`) and the segment size (16 or 32 bits). If you don’t use `.MODEL`, near pointers are the default.

In 16-bit mode, a near pointer is 2 bytes that contain the offset of the object pointed to. A far pointer requires 4 bytes, and contains both the segment and offset. In 32-bit mode, a near pointer is 4 bytes and a far pointer is 6 bytes, since segments are...
still word values in 32-bit mode. If you specify the distance with \texttt{NEAR} or \texttt{FAR}, the processor uses the default distance of the current segment size. You can use \texttt{NEAR16}, \texttt{NEAR32}, \texttt{FAR16}, and \texttt{FAR32} to override the defaults set by the current segment size. In flat model, \texttt{NEAR} is the default.

You can declare pointer variables with a pointer type created with \texttt{TYPEDEF}. Here are some examples using these pointer types.

\begin{verbatim}
; Type declarations
Array  WORD  25 DUP (0)
Msg    BYTE  "This is a string", 0
pMsg   PBYTE Msg           ; Pointer to string
pArray PWORD Array        ; Pointer to word array
npMsg  NPBYTE Msg          ; Near pointer to string
npArray NPWORD Array      ; Near pointer to word array
fpArray FPWORD Array      ; Far pointer to word array
fpMsg  FPBYTE Msg          ; Far pointer to string
S1     BYTE  "first", 0     ; Some strings
S2     BYTE  "second", 0
S3     BYTE  "third", 0
pS123  PBYTE S1, S2, S3, 0 ; Array of pointers to strings
ppS123 PPBYTE pS123        ; A pointer to pointers to strings
Andy   PERSON <>            ; Structure variable
pAndy  PPERSON Andy        ; Pointer to structure variable

; Procedure prototype
EXTERN ptrArray:PBYTE      ; External variable
Sort   PROTO pArray:PBYTE  ; Parameter for prototype

; Parameter for procedure
Sort   PROC pArray:PBYTE
       LOCAL pTmp:PBYTE ; Local variable
       .
       .
       ret
Sort   ENDP
\end{verbatim}

Once defined, pointer types can be used in any context where intrinsic types are allowed.
Defining Register Types with ASSUME

You can use the **ASSUME** directive with general-purpose registers to specify that a register is a pointer to a certain size of object. For example:

```
ASSUME bx: PTR WORD
inc [bx]     ; Increment word pointed to by BX
add bx, 2    ; Point to next word
mov [bx], 0   ; Word pointed to by BX = 0
.
.
ASSUME bx: NOTHING ; Cancel assumption
```

In this example, BX is specified as a pointer to a word. After a sequence of using BX as a pointer, the assumption is canceled by assuming **NOTHING**.

Without the assumption to **PTR WORD**, many instructions need a size specifier. The **INC** and **MOV** statements from the previous examples would have to be written like this to specify the sizes of the memory operands:

```
inc WORD PTR [bx]     ; Legal
mov WORD PTR [bx], 0
```

When you have used **ASSUME**, attempts to use the register for other purposes generate assembly errors. In this example, while the **PTR WORD** assumption is in effect, any use of BX inconsistent with its **ASSUME** declaration generates an error. For example,

```
; mov al, [bx]        ; Can't move word to byte register
```

You can also use the **PTR** operator to override defaults:

```
mov al, BYTE PTR [bx] ; Legal
```

Similarly, you can use **ASSUME** to prevent the use of a register as a pointer, or even to disable a register:

```
ASSUME bx: WORD, dx: ERROR
; mov al, [bx] ; Error - BX is an integer, not a pointer
; mov ax, dx  ; Error - DX disabled
```

For information on using **ASSUME** with segment registers, refer to “Setting the ASSUME Directive for Segment Registers” in Chapter 2.
Basic Pointer and Address Operations

A program can perform the following basic operations with pointers and addresses:

- Initialize a pointer variable by storing an address in it.
- Load an address into registers, directly or from a pointer.

The sections in the rest of this chapter describe variations of these tasks with pointers and addresses. The examples are used with the assumption that you have previously defined the following pointer types with the `TYPEDEF` directive:

```
PBYTE   TYPEDEF      PTR BYTE   ; Pointer to bytes
NPBYTE  TYPEDEF NEAR PTR BYTE   ; Near pointer to bytes
FPBYTE  TYPEDEF FAR  PTR BYTE   ; Far pointer to bytes
```

Initializing Pointer Variables

If the value of a pointer is known at assembly time, the assembler can initialize it automatically so that no processing time is wasted on the task at run time. The following example shows how to do this, placing the address of `msg` in the pointer `pmsg`.

```
Msg     BYTE    "String", 0
pMsg    PBYTE   Msg
```

If a pointer variable can be conditionally defined to one of several constant addresses, initialization must be delayed until run time. The technique is different for near pointers than for far pointers, as shown here:

```
Msg1    BYTE    "String1"
Msg2    BYTE    "String2"
npMsg   NPBYTE  ?
fpMsg   FPBYTE  ?

mov     npMsg, OFFSET Msg1              ; Load near pointer
mov     WORD PTR fpMsg[0], OFFSET Msg2  ; Load far offset
mov     WORD PTR fpMsg[2], SEG Msg2     ; Load far segment
```

If you know that the segment for a far pointer is in a register, you can load it directly:

```
mov     WORD PTR fpMsg[2], ds           ; Load segment of far pointer
```
Dynamic Addresses

Often a pointer must point to a dynamic address, meaning the address depends on a run-time condition. Typical situations include memory allocated by MS-DOS (see "Interrupt 21h Function 48h" in Help) and addresses found by the SCAS or CMPS instructions (see “Processing Strings” in Chapter 5). The following illustrates the technique for saving dynamic addresses:

```assembly
; Dynamically allocated buffer
fpBuf   FARBYTE 0               ; Initialize so offset will be zero
.
.
.
mov     ah, 48h         ; Allocate memory
mov     bx, 10h         ; Request 16 paragraphs
int     21h             ; Call DOS
jc      error           ; Return segment in AX
mov     WORD PTR fpBuf[2], ax   ; Load segment
       ; (offset is already 0)
.
.
error:                        ; Handle error
.
.
Copying Pointers

Sometimes one pointer variable must be initialized by copying from another. Here are two ways to copy a far pointer:

```assembly
fpBuf1  EXPBYTE ?
fpu2    EXPBYTE ?
.
.
.
; Copy through registers is faster, but requires a spare register
mov     ax, WORD PTR fpBuf1[0]
mov     WORD PTR fpBuf2[0], ax
mov     ax, WORD PTR fpBuf1[2]
mov     WORD PTR fpBuf2[2], ax
.
.
; Copy through stack is slower, but does not use a register
push    WORD PTR fpBuf1[0]
push    WORD PTR fpBuf1[2]
pop     WORD PTR fpBuf2[2]
pop     WORD PTR fpBuf2[0]
```
Pointers as Arguments

Most high-level-language procedures and library functions accept arguments passed on the stack. “Passing Arguments on the Stack” in Chapter 7 covers this subject in detail. A pointer is passed in the same way as any other variable, as this fragment shows:

; Push a far pointer (segment always pushed first)
push WORD PTR fpMsg[2] ; Push segment
push WORD PTR fpMsg[0] ; Push offset

Pushing an address has the same result as pushing a pointer to the address:

; Push a far address as a far pointer
mov ax, SEG fVar ; Load and push segment
push ax
mov ax, OFFSET fVar ; Load and push offset
push ax

On the 80186 and later processors, you can push a constant in one step:

push SEG fVar ; Push segment
push OFFSET fVar ; Push offset

Loading Addresses into Registers

Loading a near address into a register (or a far address into a pair of registers) is a common task in assembly-language programming. To reference data pointed to by a pointer, your program must first place the pointer into a register or pair of registers.

Load far addresses as segment:offset pairs. The following pairs have specific uses:

<table>
<thead>
<tr>
<th>Segment:Offset Pair</th>
<th>Standard Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>DS:SI</td>
<td>Source for string operations</td>
</tr>
<tr>
<td>ES:DI</td>
<td>Destination for string operations</td>
</tr>
<tr>
<td>DS:DX</td>
<td>Input for certain DOS functions</td>
</tr>
<tr>
<td>ES:BX</td>
<td>Output from certain DOS functions</td>
</tr>
</tbody>
</table>

Addresses from Data Segments

For near addresses, you need only load the offset; the segment is assumed as SS for stack-based data and as DS for other data. You must load both segment and offset for far pointers.
Here is an example of loading an address into DS:BX from a near data segment:

```
.DATA
Msg      BYTE    "String"

mov     bx, OFFSET Msg  ; Load address to BX
;   (DS already loaded)
```

Far data can be loaded like this:

```
.FARDATA
Msg      BYTE    "String"

mov     ax, SEG Msg     ; Load address to ES:BX
mov     es, ax
mov     bx, OFFSET Msg
```

You can also read a far address from a pointer in one step, using the LES and LDS instructions described next.

### Far Pointers

The LES and LDS instructions load a far pointer into a segment pair. The instructions copy the pointer’s low word into either ES or DS, and the high word into a given register. The following example shows how to load a far pointer into ES:DI:

```
OutBuf  BYTE    20 DUP (0)
fpOut   FPBYTE  OutBuf

les     di, fpOut      ; Load far pointer into ES:DI
```
Stack Variables

The technique for loading the address of a stack variable is significantly different from the technique for loading near addresses. You may need to put the correct segment value into ES for string operations. The following example illustrates how to load the address of a local (stack) variable to ES:DI:

Task    PROC
LOCAL   Arg[4]: BYTE
push    ss      ; Since it's stack-based, segment is SS
pop     es      ; Copy SS to ES
lea     di, Arg ; Load offset to DI

The local variable in this case actually evaluates to SS:[BP-4]. This is an offset from the stack frame (described in “Passing Arguments on the Stack,” Chapter 7). Since you cannot use the OFFSET operator to get the offset of an indirect memory operand, you must use the LEA (Load Effective Address) instruction.

Direct Memory Operands

To get the address of a direct memory operand, use either the LEA instruction or the MOV instruction with OFFSET. Though both methods have the same effect, the MOV instruction produces smaller and faster code, as shown in this example:

lea     si, Msg        ; Four byte instruction
mov     si, OFFSET Msg ; Three byte equivalent

Copying Between Segment Pairs

Copying from one register pair to another is complicated by the fact that you cannot copy one segment register directly to another. Two copying methods are shown here. Timings are for the 8088 processor.

; Copy DS:SI to ES:DI, generating smaller code
push    ds              ; 1 byte, 14 clocks
pop     es              ; 1 byte, 12 clocks
mov     di, si          ; 2 bytes, 2 clocks

; Copy DS:SI to ES:DI, generating faster code
mov     di, ds          ; 2 bytes, 2 clocks
mov     es, di          ; 2 bytes, 2 clocks
mov     di, si          ; 2 bytes, 2 clocks
Model-Independent Techniques

Often you may want to write code that is memory-model independent. If you are writing libraries that must be available for different memory models, you can use conditional assembly to handle different sizes of pointers. You can use the predefined symbols @DataSize and @Model to test the current assumptions.

You can use conditional assembly to write code that works with pointer variables that have no specified distance. The predefined symbol @DataSize tests the pointer size for the current memory model:

```assembly
Msg1 BYTE "String1"
pMsg PBYTE ?

IF @DataSize
   mov WORD PTR pMsg[0], OFFSET Msg1    ; Load far offset
   mov WORD PTR pMsg[2], SEG Msg1       ; Load far segment
ELSE
   mov pMsg, OFFSET Msg1                ; Load near pointer
ENDIF
```

In the following example, a procedure receives as an argument a pointer to a word variable. The code inside the procedure uses @DataSize to determine whether the current memory model supports far or near data. It loads and processes the data accordingly:

```assembly
; Procedure that receives an argument by reference
mul8 PROC arg:PTR WORD

IF @DataSize
   les bx, arg ; Load far pointer to ES:BX
   mov ax, es:[bx] ; Load the data pointed to
ELSE
   mov bx, arg ; Load near pointer to BX (assume DS)
   mov ax, [bx] ; Load the data pointed to
ENDIF

shl ax, 1 ; Multiply by 8
shl ax, 1
shl ax, 1
ret
mul8 ENDP
```
If you have many routines, writing the conditionals for each case can be tedious. The following conditional statements automatically generate the proper instructions and segment overrides.

```plaintext
; Equates for conditional handling of pointers
IF @DataSize
lesIF TEXTEQU <les>
ldsIF TEXTEQU <lds>
esIF TEXTEQU <es:>
ELSE
lesIF TEXTEQU <mov>
ldsIF TEXTEQU <mov>
esIF TEXTEQU <>
ENDIF
```

Once you define these conditionals, you can use them to simplify code that must handle several types of pointers. This next example rewrites the above `mul8` procedure to use conditional code.

```plaintext
mul8 PROC arg:PTR WORD
    lesIF bx, arg ; Load pointer to BX or ES:BX
    mov ax, esIF [bx] ; Load the data from [BX] or ES:[BX]
    shl ax, 1 ; Multiply by 8
    shl ax, 1
    ret
mul8 ENDP
```

The conditional statements from these examples can be defined once in an include file and used whenever you need to handle pointers.
CHAPTER 4

Defining and Using Simple Data Types

This chapter covers the concepts essential for working with simple data types in assembly-language programs. The first section shows how to declare integer variables. The second section describes basic operations including moving, loading, and sign-extending numbers, as well as calculating. The last section describes how to do various operations with numbers at the bit level, such as using bitwise logical instructions and shifting and rotating bits.

The complex data types introduced in the next chapter—arrays, strings, structures, unions, and records—use many of the operations illustrated in this chapter. Floating-point operations require a different set of instructions and techniques. These are covered in Chapter 6, “Using Floating-Point and Binary Coded Decimal Numbers.”

Declaring Integer Variables

An integer is a whole number, such as 4 or 4,444. Integers have no fractional part, as do the real numbers discussed in Chapter 6. You can initialize integer variables in several ways with the data allocation directives. This section explains how to use the SIZEOF and TYPE operators to provide information to the assembler about the types in your program. For information on symbolic integer constants, see “Integer Constants and Constant Expressions” in Chapter 1.

Allocating Memory for Integer Variables

When you declare an integer variable by assigning a label to a data allocation directive, the assembler allocates memory space for the integer. The variable’s name becomes a label for the memory space. The syntax is:

```
[name] directive initializer
```
The following directives indicate the integer’s size and value range:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Description of Initializers</th>
</tr>
</thead>
<tbody>
<tr>
<td>BYTE, DB (byte)</td>
<td>Allocates unsigned numbers from 0 to 255.</td>
</tr>
<tr>
<td>SBYTE (signed byte)</td>
<td>Allocates signed numbers from –128 to +127.</td>
</tr>
<tr>
<td>WORD, DW (word = 2 bytes)</td>
<td>Allocates unsigned numbers from 0 to 65,535 (64K).</td>
</tr>
<tr>
<td>SWORD (signed word)</td>
<td>Allocates signed numbers from –32,768 to +32,767.</td>
</tr>
<tr>
<td>DWORD, DD (doubleword = 4 bytes),</td>
<td>Allocates unsigned numbers from 0 to 4,294,967,295 (4 megabytes).</td>
</tr>
<tr>
<td>SDWORD (signed doubleword)</td>
<td>Allocates signed numbers from –2,147,483,648 to +2,147,483,647.</td>
</tr>
<tr>
<td>FWORD, DF (farword = 6 bytes)</td>
<td>Allocates 6-byte (48-bit) integers. These values are normally used only as pointer variables on the 80386/486 processors.</td>
</tr>
<tr>
<td>QWORD, DQ (quadword = 8 bytes)</td>
<td>Allocates 8-byte integers used with 8087-family coprocessor instructions.</td>
</tr>
<tr>
<td>TBYTE, DT (10 bytes),</td>
<td>Allocates 10-byte (80-bit) integers if the initializer has a radix specifying the base of the number.</td>
</tr>
</tbody>
</table>

See Chapter 6 for information on the REAL4, REAL8, and REAL10 directives that allocate real numbers.

The SIZEOF and TYPE operators, when applied to a type, return the size of an integer of that type. The size attribute associated with each data type is:

<table>
<thead>
<tr>
<th>Data Type</th>
<th>Bytes</th>
</tr>
</thead>
<tbody>
<tr>
<td>BYTE, SBYTE</td>
<td>1</td>
</tr>
<tr>
<td>WORD, SWORD</td>
<td>2</td>
</tr>
<tr>
<td>DWORD, SDWORD</td>
<td>4</td>
</tr>
<tr>
<td>FWORD</td>
<td>6</td>
</tr>
<tr>
<td>QWORD</td>
<td>8</td>
</tr>
<tr>
<td>TBYTE</td>
<td>10</td>
</tr>
</tbody>
</table>

The data types SBYTE, SWORD, and SDWORD tell the assembler to treat the initializers as signed data. It is important to use these signed types with high-level constructs such as .IF, .WHILE, and .REPEAT, and with PROTO and INVOKE directives. For descriptions of these directives, see the sections “Loop-Generating Directives,” “Declaring Procedure Prototypes,” and “Calling Procedures with INVOKE” in Chapter 7.
The assembler stores integers with the least significant bytes lowest in memory. Note that assembler listings and most debuggers show the bytes of a word in the opposite order—high byte first.

Figure 4.1 illustrates the integer formats.

![Integer Formats Diagram]

Although the **TYPEDEF** directive’s primary purpose is to define pointer variables (see “Defining Pointer Types with TYPEDEF” in Chapter 3), you can also use **TYPEDEF** to create an alias for any integer type. For example, these declarations

```plaintext
char    TYPEDEF SBYTE
long    TYPEDEF DWORD
float   TYPEDEF REAL4
double  TYPEDEF REAL8
```

allow you to use `char`, `long`, `float`, or `double` in your programs if you prefer the C data labels.

## Data Initialization

You can initialize variables when you declare them with constants or expressions that evaluate to constants. The assembler generates an error if you specify an initial value too large for the variable type.

A `?` in place of an initializer indicates you do not require the assembler to initialize the variable. The assembler allocates the space but does not write in it. Use `?` for buffer areas or variables your program will initialize at run time.
You can declare and initialize variables in one step with the data directives, as these examples show.

### Examples

- **integer** `BYTE 16` ; Initialize byte to 16
- **negint** `SBYTE -16` ; Initialize signed byte to -16
- **expression** `WORD 4*3` ; Initialize word to 12
- **signedexp** `SWORD 4*3` ; Initialize signed word to 12
- **empty** `QWORD ?` ; Allocate uninitialized long int
- **BYTE** `1,2,3,4,5,6` ; Initialize six unnamed bytes
- **long** `DWORD 4294967295` ; Initialize doubleword to 4,294,967,295
- **longnum** `SDWORD -2147433648` ; Initialize signed doubleword to -2,147,433,648
- **tb** `TBYTE 2345t` ; Initialize 10-byte binary number

For information on arrays and on using the **DUP** operator to allocate initializer lists, see “Arrays and Strings” in Chapter 5.

## Working with Simple Variables

Once you have declared integer variables in your program, you can use them to copy, move, and sign-extend integer variables in your MASM code. This section shows how to do these operations as well as how to add, subtract, multiply, and divide numbers and do bit-level manipulations with logical, shift, and rotate instructions.

Since MASM instructions require operands to be the same size, you may need to operate on data in a size other than that originally declared. You can do this with the **PTR** operator. For example, you can use the **PTR** operator to access the high-order word of a **DWORD**-size variable. The syntax for the **PTR** operator is

**type PTR expression**

where the **PTR** operator forces **expression** to be treated as having the type specified. An example of this use is

```
.DATA
num DWORD 0
.CODE
mov ax, WORD PTR num[0] ; Loads a word-size value from
mov dx, WORD PTR num[2] ; a doubleword variable
```
Copying Data

The primary instructions for moving data from operand to operand and loading them into registers are \texttt{MOV} (Move), \texttt{XCHG} (Exchange), \texttt{CWD} (Convert Word to Double), and \texttt{CBW} (Convert Byte to Word).

Moving Data

The most common method of moving data, the \texttt{MOV} instruction, is essentially a copy instruction, since it always copies the source operand to the destination operand without affecting the source. After a \texttt{MOV} instruction, the source and destination operands contain the same value.

The following example illustrates the \texttt{MOV} instruction. As explained in “General-Purpose Registers,” Chapter 1, you cannot move a value from one location in memory to another in a single operation.

\begin{verbatim}
; Immediate value moves
mov ax, 7       ; Immediate to register
mov mem, 7      ; Immediate to memory direct
mov mem[bx], 7  ; Immediate to memory indirect

; Register moves
mov mem, ax     ; Register to memory direct
mov mem[bx], ax ; Register to memory indirect
mov ax, bx      ; Register to register
mov ds, ax      ; General register to segment register

; Direct memory moves
mov ax, mem     ; Memory direct to register
mov ds, mem     ; Memory to segment register

; Indirect memory moves
mov ax, mem[bx] ; Memory indirect to register
mov ds, mem[bx] ; Memory indirect to segment register

; Segment register moves
mov mem, ds     ; Segment register to memory
mov mem[bx], ds ; Segment register to memory indirect
mov ax, ds      ; Segment register to general register
\end{verbatim}
The following example shows several common types of moves that require two instructions.

```
; Move immediate to segment register
    mov     ax, DGROUP  ; Load AX with immediate value
    mov     ds, ax      ; Copy AX to segment register

; Move memory to memory
    mov     ax, mem1    ; Load AX with memory value
    mov     mem2, ax    ; Copy AX to other memory

; Move segment register to segment register
    mov     ax, ds      ; Load AX with segment register
    mov     es, ax      ; Copy AX to segment register
```

The MOVSX and MOVZX instructions for the 80386/486 processors extend and copy values in one step. See “Extending Signed and Unsigned Integers,” following.

**Exchanging Integers**

The XCHG (Exchange) instruction exchanges the data in the source and destination operands. You can exchange data between registers or between registers and memory, but not from memory to memory:

```
    xchg    ax, bx       ; Put AX in BX and BX in AX
    xchg    memory, ax   ; Put "memory" in AX and AX in "memory"
;    xchg    mem1, mem2  ; Illegal - can't exchange memory locations
```

**Extending Signed and Unsigned Integers**

Since moving data between registers of different sizes is illegal, you must “sign-extend” integers to convert signed data to a larger size. Sign-extending means copying the sign bit of the unextended operand to all bits of the operand’s next larger size. This widens the operand while maintaining its sign and value.

8086-based processors provide four instructions specifically for sign-extending. The four instructions act only on the accumulator register (AL, AX, or EAX), as shown in the following list.

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Sign-extend</th>
</tr>
</thead>
<tbody>
<tr>
<td>CBW (convert byte to word)</td>
<td>AL to AX</td>
</tr>
<tr>
<td>CWD (convert word to doubleword)</td>
<td>AX to DX:AX</td>
</tr>
<tr>
<td>CWDE (convert word to doubleword extended)*</td>
<td>AX to EAX</td>
</tr>
<tr>
<td>CDQ (convert doubleword to quadword)*</td>
<td>EAX to EDX:EAX</td>
</tr>
</tbody>
</table>

*Requires an extended register and applies only to 80386/486 processors.
On the 80386/486 processors, the **CWDE** instruction converts a signed 16-bit value in AX to a signed 32-bit value in EAX. The **CDQ** instruction converts a signed 32-bit value in EAX to a signed 64-bit value in the EDX:EAX register pair.

This example converts signed integers using **CBW**, **CWD**, **CWDE**, and **CDQ**.

```
.DATA
mem8 SBYTE -5
mem16 SWORD +5
mem32 SDWORD -5
.CODE

mov al, mem8 ; Load 8-bit -5 (FBh)
cbw ; Convert to 16-bit -5 (FFFFBh) in AX
mov ax, mem16 ; Load 16-bit +5
cwd ; Convert to 32-bit +5 (0000:0005h) in DX:AX
mov ax, mem16 ; Load 16-bit +5
cwde ; Convert to 32-bit +5 (00000005h) in EAX
mov eax, mem32 ; Load 32-bit -5 (FFFFFFFBh)
cdq ; Convert to 64-bit -5
     ; (FFFFFFFF:FFFFFFFBh) in EDX:EAX
```

These four instructions efficiently convert unsigned values as well, provided the sign bit is zero. This example, for instance, correctly widens `mem16` whether you treat the variable as signed or unsigned.

The processor does not differentiate between signed and unsigned values. For instance, the value of `mem8` in the previous example is literally 251 (0FBh) to the processor. It ignores the human convention of treating the highest bit as an indicator of sign. The processor can ignore the distinction between signed and unsigned numbers because binary arithmetic works the same in either case.

If you add 7 to `mem8`, for example, the result is 258 (102h), a value too large to fit into a single byte. The byte-sized `mem8` can accommodate only the least-significant digits of the result (02h), and so receives the value of 2. The result is the same whether we treat `mem8` as a signed value (-5) or unsigned value (251).

This overview illustrates how the programmer, not the processor, must keep track of which values are signed or unsigned, and treat them accordingly. If `AL=127` (01111111y), the instruction **CBW** sets `AX=127` because the sign bit is zero. If `AL=128` (10000000y), however, the sign bit is 1. **CBW** thus sets `AX=65,280`
(FF00h), which may not be what you had in mind if you assumed AL originally held an unsigned value. To widen unsigned values, explicitly set the higher register to zero, as shown in the following example:

```assembly
; DATA
mem8 BYTE 251
mem16 WORD 251
; CODE

mov al, mem8  ; Load 251 (FBh) from 8-bit memory
sub ah, ah    ; Zero upper half (AH)

mov ax, mem16 ; Load 251 (FBh) from 16-bit memory
sub dx, dx    ; Zero upper half (DX)
sub eax, eax  ; Zero entire extended register (EAX)

mov ax, mem16 ; Load 251 (FBh) from 16-bit memory
```

The 80386/486 processors provide instructions that move and extend a value to a larger data size in a single step. **MOVZX** moves an unsigned value into a register and zero-extends it. **MOVsx** moves a signed value into a register and sign-extends it.

```assembly
; 80386/486 instructions
movzx dx, bl      ; Load unsigned 8-bit value into 16-bit register and zero-extend
```

These special 80386/486 instructions usually execute much faster than the equivalent 8086/286 instructions.

### Adding and Subtracting Integers

You can use the **ADD**, **ADC**, **INC**, **SUB**, **SBB**, and **DEC** instructions for adding, incrementing, subtracting, and decrementing values in single registers. You can also combine them to handle larger values that require two registers for storage.

#### Adding and Subtracting Integers Directly

The **ADD**, **INC** (Increment), **SUB**, and **DEC** (Decrement) instructions operate on 8- and 16-bit values on the 8086–80286 processors, and on 8-, 16-, and 32-bit values on the 80386/486 processors. They can be combined with the **ADC** and **SBB** instructions to work on 32-bit values on the 8086 and 64-bit values on the 80386/486 processors. (See “Adding and Subtracting in Multiple Registers,” following.)
These instructions have two requirements:

1. If there are two operands, only one operand can be a memory operand.
2. If there are two operands, both must be the same size.

To meet the second requirement, you can use the **PTR** operator to force an operand to the size required. (See “Working with Simple Variables,” previous.) For example, if **Buffer** is an array of bytes and BX points to an element of the array, you can add a word from **Buffer** with

```
add    ax, WORD PTR Buffer[bx] ; Add word from byte array
```

The next example shows 8-bit signed and unsigned addition and subtraction.

```
; .DATA
mem8   BYTE    39
.CODE

; Addition
mov    al, 26   ; Start with register     26     26
inc    al       ; Increment              1       1
add    al, 76   ; Add immediate         76     + 76
    ;       ;                      ----     ----
add    al, mem8 ; Add memory            39     + 39
    ;       ;                      ----     ----
mov    ah, al   ; Copy to AH          -114     142
    ; +overflow
add    al, ah   ; Add register                  142
    ;     ;                                28+carry

; Subtraction
mov    al, 95   ; Load register         95     95
dec    al       ; Decrement             -1      -1
sub    al, 23   ; Subtract immediate    -23     -23
    ;       ;                      ----     ----
    ;       ;                      ----     ----
sub    al, mem8 ; Subtract memory     -122     -122
    ;       ;                      ----     ----
    ;       ;                      ----     ----
mov    ah, 119  ; Load register        119
sub    al, ah   ; and subtract       -51      205+sign
    ;       ;                      ----     ----
    ;       ;                           86+overflow

```

The **INC** and **DEC** instructions treat integers as unsigned values and do not update the carry flag for signed carries and borrows.

When the sum of 8-bit signed operands exceeds 127, the processor sets the overflow flag. (The overflow flag is also set if both operands are negative and the sum is less than or equal to -128.) Placing a **JO** (Jump on Overflow) or **INTO** (Interrupt on Overflow) instruction in your program at this point can transfer control to error-recovery statements. When the sum exceeds 255, the processor sets the carry flag. A **JC** (Jump on Carry) instruction at this point can transfer control to error-recovery statements.

In the previous subtraction example, the processor sets the sign flag if the result goes below 0. At this point, you can use a **JS** (Jump on Sign) instruction to transfer control to error-recovery statements. Jump instructions are described in the “Jumps” section in Chapter 7.

### Adding and Subtracting in Multiple Registers

You can add and subtract numbers larger than the register size on your processor with the **ADC** (Add with Carry) and **SBB** (Subtract with Borrow) instructions. If the operations prior to an **ADC** or **SBB** instruction do not set the carry flag, these instructions are identical to **ADD** and **SUB**. When you operate on large values in more than one register, use **ADD** and **SUB** for the least significant part of the number and **ADC** or **SBB** for the most significant part.

The following example illustrates multiple-register addition and subtraction. You can also use this technique with 64-bit operands on the 80386/486 processors.

```
.DAT
mem82  DWORD  316423
mem82a DWORD  316423
mem82b DWORD  156739
.CODE
.
.
.
; Addition
mov   ax, 43981               ; Load immediate 43981
sub   dx, dx                  ;     into DX:AX
add   ax, WORD PTR mem32[0]   ;     + 316423
adc   dx, WORD PTR mem32[2]   ;     memory words
     ;     Result in DX:AX 360404
; Subtraction
mov   ax, WORD PTR mem82a[0]  ; Load mem82 316423
mov   dx, WORD PTR mem82a[2]  ;     into DX:AX
sub   ax, WORD PTR mem82b[0]  ;     Subtract low - 156739
sbb   dx, WORD PTR mem82b[2]  ;     then high
     ;     Result in DX:AX 159684
```
For 32-bit registers on the 80386/486 processors, only two steps are necessary. If your program needs to be assembled for more than one processor, you can assemble the statements conditionally, as shown in this example:

```
.DATA
mem32    DWORD  316423
mem32a   DWORD  316423
mem32b   DWORD  156739
p386     TEXTEQU (@Cpu AND 08h)
.CODE

; Addition
IF      p386
    mov     eax, 43981  ; Load immediate
    add     eax, mem32  ; Result in EAX
ELSE
    ; do steps in previous example
ENDIF

; Subtraction
IF      p386
    mov     eax, mem32a ; Load memory
    sub     eax, mem32b ; Result in EAX
ELSE
    ; do steps in previous example
ENDIF
```

Since the status of the carry flag affects the results of calculations with ADC and SBB, be sure to turn off the carry flag with the CLC (Clear Carry Flag) instruction or use ADD or SUB for the first calculation, when appropriate.

### Multiplying and Dividing Integers

The 8086 family of processors uses different multiplication and division instructions for signed and unsigned integers. Multiplication and division instructions also have special requirements depending on the size of the operands and the processor the code runs on.

#### Using Multiplication Instructions

The **MUL** instruction multiplies unsigned numbers. **IMUL** multiplies signed numbers. For both instructions, one factor must be in the accumulator register (AL for 8-bit numbers, AX for 16-bit numbers, EAX for 32-bit numbers). The
other factor can be in any single register or memory operand. The result overwrites the contents of the accumulator register.

Multiplying two 8-bit numbers produces a 16-bit result returned in AX. Multiplying two 16-bit operands yields a 32-bit result in DX:AX. The 80386/486 processor handles 64-bit products in the same way in the EDX:EAX pair.

This example illustrates multiplication of signed 16- and 32-bit integers.

```
; 8-bit unsigned multiply
mov al, 23 ; Load AL                    23
mov bl, 24 ; Load BL                   * 24
mul bl     ; Multiply BL              -----
; Product in AX              552
;   overflow and carry set

; 16-bit signed multiply
mov ax, 50 ; Load AX                     50
            ;                         -30000
imul mem16 ; Multiply memory          -----
; Product in DX:AX      -1500000
;   overflow and carry set
```

A nonzero number in the upper half of the result (AH for byte, DX or EDX for word) sets the overflow and carry flags.

On the 80186–80486 processors, the IMUL instruction supports three additional operand combinations. The first syntax option allows for 16-bit multipliers producing a 16-bit product or 32-bit multipliers for 32-bit products on the 80386/486. The result overwrites the destination. The syntax for this operation is:

**IMUL register16, immediate**

The second syntax option specifies three operands for IMUL. The first operand must be a 16-bit register operand, the second a 16-bit memory (or register) operand, and the third a 16-bit immediate operand. IMUL multiplies the memory (or register) and immediate operands and stores the product in the register operand with this syntax:

**IMUL register16, { memory16 | register16 }, immediate**
For the 80386/486 only, a third option for **IMUL** allows an additional operand for multiplication of a register value by a register or memory value. The syntax is:

**IMUL register,{register | memory}**

The destination can be any 16-bit or 32-bit register. The source must be the same size as the destination.

In all of these options, products too large to fit in 16 or 32 bits set the overflow and carry flags. The following examples show these three options for **IMUL**.

```assembly
imul    dx, 456  ; Multiply DX times 456 on 80186-80486
imul    ax, [bx],6  ; Multiply the value pointed to by BX by 6 and put the result in AX
imul    dx, ax      ; Multiply DX times AX on 80386
imul    ax, [bx]    ; Multiply AX by the value pointed to by BX on 80386
```

The **IMUL** instruction with multiple operands can be used for either signed or unsigned multiplication, since the 16-bit product is the same in either case. To get a 32-bit result, you must use the single-operand version of **MUL** or **IMUL**.

### Using Division Instructions

The **DIV** instruction divides unsigned numbers, and **IDIV** divides signed numbers. Both return a quotient and a remainder.

Table 4.1 summarizes the division operations. The dividend is the number to be divided, and the divisor is the number to divide by. The quotient is the result. The divisor can be in any register or memory location except the registers where the quotient and remainder are returned.

<table>
<thead>
<tr>
<th>Size of Operand</th>
<th>Dividend Register</th>
<th>Size of Divisor</th>
<th>Quotient</th>
<th>Remainder</th>
</tr>
</thead>
<tbody>
<tr>
<td>16 bits</td>
<td>AX</td>
<td>8 bits</td>
<td>AL</td>
<td>AH</td>
</tr>
<tr>
<td>32 bits</td>
<td>DX:AX</td>
<td>16 bits</td>
<td>AX</td>
<td>DX</td>
</tr>
<tr>
<td>64 bits (80386 and 80486)</td>
<td>EDX:EAX</td>
<td>32 bits</td>
<td>EAX</td>
<td>EDX</td>
</tr>
</tbody>
</table>
Unsigned division does not require careful attention to flags. The following examples illustrate signed division, which can be more complex.

```plaintext
; Divide 16-bit unsigned by 8-bit
mov ax, 700               ; Load dividend
mov bl, 36                ; Load divisor
div bl                    ; Divide BL
; Quotient in AL        19
; Remainder in AH       16

; Divide 32-bit signed by 16-bit
mov ax, WORD PTR mem32[0] ; Load into DX:AX
mov dx, WORD PTR mem32[2] ;                   500000
idiv mem16                ;              DIV -2000
; Divide memory          -----
; Quotient in AX   -250
; Remainder in DX    0

; Divide 16-bit signed by 16-bit
mov ax, WORD PTR mem16    ; Load into AX     -2000
cwd                           ; Extend to DX:AX
mov bx,-421               ;               DIV -421
idiv bx                    ; Divide by BX     -----
; Quotient in AX       4
; Remainder in DX   -316

If the dividend and divisor are the same size, sign-extend or zero-extend the dividend so that it is the length expected by the division instruction. See “Extending Signed and Unsigned Integers,” earlier in this chapter.

Manipulating Numbers at the Bit Level

The instructions introduced so far in this chapter access numbers at the byte or word level. The logical, shift, and rotate instructions described in this section access individual bits in a number. You can use logical instructions to evaluate characters and do other text and screen operations. The shift and rotate instructions do similar tasks by shifting and rotating bits through registers. This section reviews some applications of these bit-level operations.
Logical Instructions

The logical instructions **AND**, **OR**, and **XOR** compare bits in two operands. Based on the results of the comparisons, the instructions alter bits in the first (destination) operand. The logical instruction **NOT** also changes bits, but operates on a single operand.

The following list summarizes these four logical instructions. The list makes reference to the “destination bit,” meaning the bit in the destination operand. The terms “both bits” and “either bit” refer to the corresponding bits in the source and destination operands. These instructions include:

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Sets Destination Bit If</th>
<th>Clears Destination Bit If</th>
</tr>
</thead>
<tbody>
<tr>
<td>AND</td>
<td>Both bits set</td>
<td>Either or both bits clear</td>
</tr>
<tr>
<td>OR</td>
<td>Either or both bits set</td>
<td>Both bits clear</td>
</tr>
<tr>
<td>XOR</td>
<td>Either bit (but not both) set</td>
<td>Both bits set or both clear</td>
</tr>
<tr>
<td>NOT</td>
<td>Destination bit clear</td>
<td>Destination bit set</td>
</tr>
</tbody>
</table>

**Note**  Do not confuse logical instructions with the logical operators, which perform these operations at assembly time, not run time. Although the names are the same, the assembler recognizes the difference.

The following example shows the result of the **AND**, **OR**, **XOR**, and **NOT** instructions operating on a value in the AX register and in a mask. A mask is any number with a pattern of bits set for an intended operation.

```
mov ax, 035h ; Load value
and ax, 0FBh ; Clear bit 2
            ; AND 11111011
            ; ---------
            ; Value is now 31h
or ax, 016h ; Set bits 4,2,1
            ; OR 00010110
            ; ---------
            ; Value is now 37h
xor ax, 0ADh ; Toggle bits 7,5,3,2,0
            ; XOR 10101101
            ; ---------
            ; Value is now 9Ah
not ax ; Value is now 65h
            ; NOT 01100101
```

The **AND** instruction clears unmasked bits—that is, bits not protected by 1 in the mask. To mask off certain bits in an operand and clear the others, use an appropriate masking value in the source operand. The bits of the mask should be 0 for any bit positions you want to clear and 1 for any bit positions you want to remain unchanged.
The **OR** instruction forces specific bits to 1 regardless of their current settings. The bits of the mask should be 1 for any bit positions you want to set and 0 for any bit positions you want to remain unchanged.

The **XOR** instruction toggles the value of specific bits on and off—that is, reverses them from their current settings. This instruction sets a bit to 1 if the corresponding bits are different or to 0 if they are the same. The bits of the mask should be 1 for any bit positions you want to toggle and 0 for any bit positions you want to remain unchanged.

The following examples show an application for each of these instructions. The code illustrating the **AND** instruction converts a “y” or “n” read from the keyboard to uppercase, since bit 5 is always clear in uppercase letters. In the example for **OR**, the first statement is faster and uses fewer bytes than `cmp bx, 0`. When the operands for **XOR** are identical, each bit cancels itself, producing 0.

```assembly
; AND example - converts characters to uppercase
mov ah, 7           ; Get character without echo
int 21h
and al, 11011111y   ; Convert to uppercase by clearing bit 5
cmp al, 'Y'         ; Is it Y?
je yes              ; If so, do Yes actions
.                   ; Else do No actions
yes:
.
```

```assembly
; OR example - compares operand to 0
or bx, bx           ; Compare to 0
jg positive         ; BX is positive
jl negative         ; BX is negative
.
; XOR example - sets a register to 0
xor cx, cx          ; 2 bytes, 3 clocks on 8088
sub cx, cx          ; 2 bytes, 3 clocks on 8088
mov cx, 0           ; 3 bytes, 4 clocks on 8088
```

On the 80386/486 processors, the **BSF** (Bit Scan Forward) and the **BSR** (Bit Scan Reverse) instructions perform operations like those of the logical instructions. They scan the contents of a register to find the first-set or last-set bit. You can use **BSF** or **BSR** to find the position of a set bit in a mask or to check if a register value is 0.

### Shifting and Rotating Bits

The 8086-based processors provide a complete set of instructions for shifting and rotating bits. Shift instructions move bits a specified number of places to the
right or left. The last bit in the direction of the shift goes into the carry flag, and the first bit is filled with 0 or with the previous value of the first bit.

Rotate instructions also move bits a specified number of places to the right or left. For each bit rotated, the last bit in the direction of the rotate operation moves into the first bit position at the other end of the operand. With some variations, the carry bit is used as an additional bit of the operand. Figure 4.2 illustrates the eight variations of shift and rotate instructions for 8-bit operands. Notice that \textit{SHL} and \textit{SAL} are identical.
Figure 4.2  Shifts and Rotates

All shift instructions use the same format. Before the instruction executes, the
destination operand contains the value to be shifted; after the instruction
executes, it contains the shifted operand. The source operand contains the
number of bits to shift or rotate. It can be the immediate value 1 or the CL
register. The 8088 and 8086 processors do not accept any other values or
registers with these instructions.

Starting with the 80186 processor, you can use 8-bit immediate values larger
than 1 as the source operand for shift or rotate instructions, as shown here:

\[
\text{shr } bx, 4 ; \text{ 9 clocks, 3 bytes on 80286}
\]

The following statements are equivalent if the program must run on the 8088 or
8086 processor:

\[
\text{mov } cl, 4 ; \text{ 2 clocks, 3 bytes on 80286}
\text{shr } bx, cl ; \text{ 9 clocks, 2 bytes on 80286}
; \text{ 11 clocks, 5 bytes total}
\]

Masks for logical instructions can be shifted to new bit positions. For example,
an operand that masks off a bit or group of bits can be shifted to move the mask
to a different position, allowing you to mask off a different bit each time the
mask is used. This technique, illustrated in the following example, is useful only
if the mask value is unknown until run time.

\[
\text{DATA}
\text{masker BYTE 00000010y ; Mask that may change at run time}
\text{CODE}

\text{mov cl, 2 ; Rotate two at a time}
\text{mov bl, 57h ; Load value to be changed 01010111y}
\text{rol masker, cl ; Rotate two to left 00001000y}
\text{or bl, masker ; Turn on masked values ---------}
; New value is 05Fh 01011111y}
\text{rol masker, cl ; Rotate two more 00100000y}
\text{or bl, masker ; Turn on masked values ---------}
; New value is 07Fh 01111111y}
\]

Multiplying and Dividing with Shift Instructions

You can use the shift and rotate instructions (\text{SHR, SHL, SAR, and SAL}) for
multiplication and division. Shifting a value right by one bit has the effect of
dividing by two; shifting left by 1 bit has the effect of multiplying by two. You
can take advantage of shifts to do fast multiplication and division by powers of
two. For example, shifting left twice multiplies by four, shifting left three times multiplies by eight, and so on.

Use SHR (Shift Right) to divide unsigned numbers. You can use SAR (Shift Arithmetic Right) to divide signed numbers, but SAR rounds negative numbers down—IDIV always rounds negative numbers up (toward 0). Division using SAR must adjust for this difference. Multiplication by shifting is the same for signed and unsigned numbers, so you can use either SAL or SHL.

Multiply and divide instructions are relatively slow, particularly on the 8088 and 8086 processors. When multiplying or dividing by a power of two, use shifts to speed operations by a factor of 10 or more. For example, these statements take only four clocks on an 8088 or 8086 processor:

```
sub ah, ah    ; Clear AH
shl ax, 1     ; Multiply byte in AL by 2
```

The following statements produce the same results, but take between 74 and 81 clocks on the 8088 or 8086 processors. The same statements take 15 clocks on the 80286 and between 11 and 16 clocks on the 80386. (For a discussion about instruction timings, see “A Word on Instruction Timings” in the Introduction.)

```
mov bl, 2     ; Multiply byte in AL by 2
mul bl
```

As the following macro shows, it’s possible to multiply by any number—in this case, 10—without resorting to the MUL instruction. However, such a procedure is no more than an interesting arithmetic exercise, since the additional code almost certainly takes more time to execute than a single MUL. You should consider using shifts in your program only when multiplying or dividing by a power of two.

```
mul_10 MACRO factor       ; Factor must be unsigned
  mov ax, factor   ; Load into AX
  shl ax, 1        ; AX = factor * 2
  mov bx, ax       ; Save copy in BX
  shl ax, 1        ; AX = factor * 4
  add ax, bx       ; AX = (factor * 8) + (factor * 2)
  ENDM
```

Here’s another macro that divides by 512. In contrast to the previous example, this macro uses little code and operates faster than an equivalent DIV instruction.
div_512 MACRO dividend ; Dividend must be unsigned
    mov ax, dividend ; Load into AX
    shr ax, 1 ; AX = dividend / 2 (unsigned)
    xchg al, ah ; XCHG is like rotate right 8
                 ; AL = (dividend / 2) / 256
    cbw ; Clear upper byte
ENDM ; AX = (dividend / 512)

If you need to shift a value that is too large to fit in one register, you can shift each part separately. The RCR (Register Carry Right) and RCL (Register Carry Left) instructions carry values from the first register to the second by passing the leftmost or rightmost bit through the carry flag.

This example shifts a multiword value.

    .DATA
    mem32    DWORD 500000
    .CODE
    ; Divide 32-bit unsigned by 16
    mov cx, 4 ; Shift right 4
    again:  shr WORD PTR mem32[2], 1 ; Shift into carry
    div    16
    rcr     WORD PTR mem32[0], 1 ; Rotate carry in
    loop again
    ; Since the carry flag is treated as part of the operand (it's like using a 9-bit or 17-bit operand), the flag value before the operation is crucial. The carry flag can be adjusted by a previous instruction, but you can also set or clear the flag directly with the CLC (Clear Carry Flag), CMC (Complement Carry Flag), and STC (Set Carry Flag) instructions.

On the 80386 and 80486 processors, an alternate method for multiplying quickly by constants takes advantage of the LEA (Load Effective Address) instruction and the scaling of indirect memory operands. By using a 32-bit value as both the index and the base register in an indirect memory operand, you can multiply by the constants 2, 3, 4, 5, 8, and 9 more quickly than you can by using the MUL instruction. LEA calculates the offset of the source operand and stores it into the destination register, EBX, as this example shows:

    lea ebx, [eax*2] ; EBX = 2 * EAX
    lea ebx, [eax*2+eax] ; EBX = 3 * EAX
    lea ebx, [eax*4] ; EBX = 4 * EAX
    lea ebx, [eax*4+eax] ; EBX = 5 * EAX
    lea ebx, [eax*8] ; EBX = 8 * EAX
    lea ebx, [eax*8+eax] ; EBX = 9 * EAX

Scaling of 80386 indirect memory operands is reviewed in “Indirect Memory Operands with 32-Bit Registers” in Chapter 3. LEA is introduced in “Loading Addresses into Registers” in Chapter 3.
The next chapter deals with more complex data types—arrays, strings, structures, unions, and records. Many of the operations presented in this chapter can also be applied to the data structures covered in Chapter 5, “Defining and Using Complex Data Types.”
CHAPTER 5

Defining and Using Complex Data Types

With the complex data types available in MASM 6.1—arrays, strings, records, structures, and unions—you can access data as a unit or as individual elements that make up a unit. The individual elements of complex data types are often the integer types discussed in Chapter 4, “Defining and Using Simple Data Types.”

“Arrays and Strings” reviews how to declare, reference, and initialize arrays and strings. This section summarizes the general steps needed to process arrays and strings and describes the MASM instructions for moving, comparing, searching, loading, and storing.

“Structures and Unions” covers similar information for structures and unions: how to declare structure and union types, how to define structure and union variables, and how to reference structures and unions and their fields.

“Records” explains how to declare record types, define record variables, and use record operators.

Arrays and Strings

An array is a sequential collection of variables, all of the same size and type, called “elements.” A string is an array of characters. For example, in the string “ABC,” each letter is an element. You can access the elements in an array or string relative to the first element. This section explains how to handle arrays and strings in your programs.

Declaring and Referencing Arrays

Array elements occupy memory contiguously, so a program references each element relative to the start of the array. To declare an array, supply a label name, the element type, and a series of initializing values or ? placeholders. The following examples declare the arrays \texttt{warray} and \texttt{xarray}:

\begin{verbatim}
  warray  WORD    1, 2, 3, 4
  xarray  DWORD   0FFFFFFFFh, 789ABCDEh
\end{verbatim}
Initializer lists of array declarations can span multiple lines. The first initializer must appear on the same line as the data type, all entries must be initialized, and, if you want the array to continue to the new line, the line must end with a comma. These examples show legal multiple-line array declarations:

```
big   BYTE    21, 22, 23, 24, 25,
      26, 27, 28

somelist  WORD   10,
           20,
           30
```

If you do not use the LENGTHOF and SIZEOF operators discussed later in this section, an array may span more than one logical line, although a separate type declaration is needed on each logical line:

```
var1   BYTE    10, 20, 30
       BYTE    40, 50, 60
       BYTE    70, 80, 90
```

**The DUP Operator**

You can also declare an array with the DUP operator. This operator works with any of the data allocation directives described in “Allocating Memory for Integer Variables” in Chapter 4. In the syntax

```
count DUP (initialvalue [, initialvalue]...)
```

the `count` value sets the number of times to repeat all values within the parentheses. The `initialvalue` can be an integer, character constant, or another DUP operator, and must always appear within parentheses. For example, the statement

```
barray BYTE    5 DUP (1)
```

allocates the integer 1 five times for a total of 5 bytes.

The following examples show various ways to allocate data elements with the DUP operator:

```
array  DWORD   10 DUP (1) ; 10 doublewords ; initialized to 1
buffer BYTE    256 DUP (?) ; 256-byte buffer
masks BYTE    20 DUP (040h, 020h, 04h, 02h) ; 80-byte buffer ; with bit masks
three_d DWORD  5 DUP (5 DUP (5 DUP (0))) ; 125 double words ; initialized to 0
```
Referencing Arrays

Each element in an array is referenced with an index number, beginning with zero. The array index appears in brackets after the array name, as in

array[9]

Assembly-language indexes differ from indexes in high-level languages, where the index number always corresponds to the element's position. In C, for example, array[9] references the array's tenth element, regardless of whether each element is 1 byte or 8 bytes in size.

In assembly language, an element's index refers to the number of bytes between the element and the start of the array. This distinction can be ignored for arrays of byte-sized elements, since an element's position number matches its index. For example, defining the array

prime BYTE 1, 3, 5, 7, 11, 13, 17

gives a value of 1 to prime[0], a value of 3 to prime[1], and so forth.

However, in arrays with elements larger than 1 byte, index numbers (except zero) do not correspond to an element's position. You must multiply an element's position by its size to determine the element's index. Thus, for the array

wprime WORD 1, 3, 5, 7, 11, 13, 17

wprime[4] represents the third element (5), which is 4 bytes from the beginning of the array. Similarly, the expression wprime[6] represents the fourth element (7) and wprime[10] represents the sixth element (13).

The following example determines an index at run time. It multiplies the position by two (the size of a word element) by shifting it left:

```
mov     si, cx          ; CX holds position number
shl     si, 1           ; Scale for word referencing
mov     ax, wprime[si]  ; Move element into AX
```

The offset required to access an array element can be calculated with the following formula:

nth element of array = array[(n-1) * size of element]

Referencing an array element by distance rather than position is not difficult to master, and is actually very consistent with how assembly language works. Recall that a variable name is a symbol that represents the contents of a particular address in memory. Thus, if the array wprime begins at address DS:2400h, the reference wprime[6] means to the processor “the word value contained in the DS segment at offset 2400h-plus-6-bytes.”
As described in “Direct Memory Operands,” Chapter 3, you can substitute the plus operator (+) for brackets, as in:

\[ wprime[9] \]
\[ wprime+9 \]

Since brackets simply add a number to an address, you don’t need them when referencing the first element. Thus, \[ wprime \] and \[ wprime[0] \] both refer to the first element of the array \( wprime \).

If your program runs only on an 80186 processor or higher, you can use the BOUND instruction to verify that an index value is within the bounds of an array. For a description of BOUND, see the Reference.

LENGTHOF, SIZEOF, and TYPE for Arrays

When applied to arrays, the LENGTHOF, SIZEOF, and TYPE operators return information about the length and size of the array and about the type of the initializers.

The LENGTHOF operator returns the number of elements in the array. The SIZEOF operator returns the number of bytes used by the initializers in the array definition. TYPE returns the size of the elements of the array. The following examples illustrate these operators:

```
array  WORD    40 DUP (5)
larray EQU     LENGTHOF array     ; 40 elements
sarray EQU     SIZEOF   array     ; 80 bytes
tarray EQU     TYPE     array     ; 2 bytes per element
num     DWORD   4, 5, 6, 7, 8, 9, 10, 11
lnum    EQU     LENGTHOF num      ;  8 elements
snum    EQU     SIZEOF   num      ; 32 bytes
tnum    EQU     TYPE     num      ;  4 bytes per element
warray  WORD    40 DUP (40 DUP (5))
len     EQU     LENGTHOF warray    ; 1600 elements
siz     EQU     SIZEOF   warray    ; 3200 bytes
typ     EQU     TYPE     warray    ;  2 bytes per element
```

Declaring and Initializing Strings

A string is an array of characters. Initializing a string like "Hello, there" allocates and initializes 1 byte for each character in the string. An initialized string can be no longer than 255 characters.
For data directives other than **BYTE**, a string may initialize only the first element. The initializer value must fit into the specified size and conform to the expression word size in effect (see “Integer Constants and Constant Expressions” in Chapter 1), as shown in these examples:

```
    wstr   WORD   "OK"
    dstr   DWORD  "DATA" ; Legal under EXPR32 only
```

As with arrays, string initializers can span multiple lines. The line must end with a comma if you want the string to continue to the next line.

```
    strm   BYTE   "This is a long string that does not ",
                  "fit on one line."
```

You can also have an array of pointers to strings.

```
PBYTE   TYPEDEF PTR BYTE
.DATA
msg1    BYTE   "Operation completed successfully."
msg2    BYTE   "Unknown command"
msg3    BYTE   "File not found"
pmsg   PBYTE   msg1            ; pmsg is an array
        msg2            ;   of pointers to
        msg3            ;   above messages
```

Strings must be enclosed in single (') or double ("" ) quotation marks. To put a single quotation mark inside a string enclosed by single quotation marks, use two single quotation marks. Likewise, if you need quotation marks inside a string enclosed by double quotation marks, use two sets. These examples show the various uses of quotation marks:

```
char    BYTE   'a'
message BYTE   "That's the message." ; That's the message.
warn    BYTE   'Can't find file.'     ; Can't find file.
string  BYTE   "This ""value"" not found." ; This "value" not found.
```

You can always use single quotation marks inside a string enclosed by double quotation marks, as the initialization for `message` shows, and vice versa.

**The ? Initializer**

You do not have to initialize an array. The ? operator lets you allocate space for the array without placing specific values in it. Object files contain records for initialized data. Unspecified space left in the object file means that no records contain initialized data for that address. The actual values stored in arrays allocated with ? depend on certain conditions. The ? initializer is treated as a zero in a **DUP** statement that contains initializers in addition to the ? initializer. If the ? initializer does not appear in a **DUP** statement, or if the **DUP** statement contains only ? initializers, the assembler leaves the allocated space unspecified.
LENGTHOF, SIZEOF, and TYPE for Strings

Because strings are simply arrays of byte elements, the `LENGTHOF`, `SIZEOF`, and `TYPE` operators behave as you would expect, as illustrated in this example:

```assembly
msg       BYTE    "This string extends ",
          "over three ",
          "lines."

lmsg      EQU     LENGTHOF msg ; 37 elements
smsg      EQU     SIZEOF   msg    ; 37 bytes
tmsg      EQU     TYPE     msg    ; 1 byte per element
```

Processing Strings

The 8086-family instruction set has seven string instructions for fast and efficient processing of entire strings and arrays. The term “string” in “string instructions” refers to a sequence of elements, not just character strings. These instructions work directly only on arrays of bytes and words on the 8086–80486 processors, and on arrays of bytes, words, and doublewords on the 80386/486 processors. Processing larger elements must be done indirectly with loops.

The following list gives capsule descriptions of the five instructions discussed in this section.

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>MOVVS</td>
<td>Copies a string from one location to another</td>
</tr>
<tr>
<td>STOS</td>
<td>Stores contents of the accumulator register to a string</td>
</tr>
<tr>
<td>CMPS</td>
<td>Compares one string with another</td>
</tr>
<tr>
<td>LODS</td>
<td>Loads values from a string to the accumulator register</td>
</tr>
<tr>
<td>SCAS</td>
<td>Scans a string for a specified value</td>
</tr>
</tbody>
</table>

All of these instructions use registers in a similar way and have a similar syntax. Most are used with the repeat instruction prefixes `REP`, `REPE` (or `REPNZ`), and `REPNE` (or `REPNZ`). `REP` is a synonym for `REPE` (Repeat While Equal) and `REPNZ` is a synonym for `REPNE` (Repeat While Not Equal).

This section first explains the general procedures for using all string instructions. It then illustrates each instruction with an example.

Overview of String Instructions

The string instructions have specific requirements for the location of strings and the use of registers. To operate on any string, follow these three steps:

1. Set the direction flag to indicate the direction in which you want to process the string. The `STD` instruction sets the flag, while `CLD` clears it.
If the direction flag is clear, the string is processed upward (from low addresses to high addresses, which is from left to right through the string). If the direction flag is set, the string is processed downward (from high addresses to low addresses, or from right to left). Under MS-DOS, the direction flag is normally clear if your program has not changed it.

2. Load the number of iterations for the string instruction into the CX register.

   If you want to process 100 elements in a string, move 100 into CX. If you wish the string instruction to terminate conditionally (for example, during a search when a match is found), load the maximum number of iterations that can be performed without an error.

3. Load the starting offset address of the source string into DS:SI and the starting address of the destination string into ES:DI. Some string instructions take only a destination or source, not both (see Table 5.1).

   Normally, the segment address of the source string should be DS, but you can use a segment override to specify a different segment for the source operand. You cannot override the segment address for the destination string. Therefore, you may need to change the value of ES. For information on changing segment registers, see “Programming Segmented Addresses” in Chapter 3.

   **Note** Although you can use a segment override on the source operand, a segment override combined with a repeat prefix can cause problems in certain situations on all processors except the 80386/486. If an interrupt occurs during the string operation, the segment override is lost and the rest of the string operation processes incorrectly. Segment overrides can be used safely when interrupts are turned off or with the 80386/486 processors.

   You can adapt these steps to the requirements of any particular string operation. The syntax for the string instructions is:

   ```
   \[[prefix]\] CMPS \[[segmentregister:]\] source, \[[ES:]\] destination
   LODS \[[segmentregister:]\] source
   \[[prefix]\] MOV\S \[[ES:]\] destination, \[[segmentregister:]\] source
   \[[prefix]\] SCAS \[[ES:]\] destination
   \[[prefix]\] STOS \[[ES:]\] destination
   ```

   Some instructions have special forms for byte, word, or doubleword operands. If you use the form of the instruction that ends in B (BYTE), W (WORD), or D (DWORD) with LODS, SCAS, and STOS, the assembler knows whether the element is in the AL, AX, or EAX register. Therefore, these instruction forms do not require operands.
Table 5.1 lists each string instruction with the type of repeat prefix it uses and indicates whether the instruction works on a source, a destination, or both.

Table 5.1  Requirements for String Instructions

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Repeat Prefix</th>
<th>Source/Destination</th>
<th>Register Pair</th>
</tr>
</thead>
<tbody>
<tr>
<td>MOV$S$</td>
<td>REP</td>
<td>Both</td>
<td>DS:SI, ES:DI</td>
</tr>
<tr>
<td>SCAS</td>
<td>REPE/REPNE</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>CMP$S$</td>
<td>REPE/REPNE</td>
<td>Both</td>
<td>DS:SI, ES:DI</td>
</tr>
<tr>
<td>LOD$S$</td>
<td>None</td>
<td>Source</td>
<td>DS:SI</td>
</tr>
<tr>
<td>STOS</td>
<td>REP</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>INS</td>
<td>REP</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>OUT$S$</td>
<td>REP</td>
<td>Source</td>
<td>DS:SI</td>
</tr>
</tbody>
</table>

The repeat prefix causes the instruction that follows it to repeat for the number of times specified in the count register or until a condition becomes true. After each iteration, the instruction increments or decrements SI and DI so that it points to the next array element. The direction flag determines whether SI and DI are incremented (flag clear) or decremented (flag set). The size of the instruction determines whether SI and DI are altered by 1, 2, or 4 bytes each time.

Each prefix governs the number of repetitions as follows:

<table>
<thead>
<tr>
<th>Prefix</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>REP</td>
<td>Repeats instruction CX times</td>
</tr>
<tr>
<td>REPE, REPZ</td>
<td>Repeats instruction maximum CX times while values are equal</td>
</tr>
<tr>
<td>REPNE, REPNZ</td>
<td>Repeats instruction maximum CX times while values are not equal</td>
</tr>
</tbody>
</table>

The prefixes apply to only one string instruction at a time. To repeat a block of instructions, use a loop construction. (See “Loops” in Chapter 7.)

At run time, if a string instruction is preceded by a repeat sequence, the processor:

1. Checks the CX register and exits if CX is 0.
2. Performs the string operation once.
3. Increases SI and/or DI if the direction flag is clear. Decreases SI and/or DI if the direction flag is set. The amount of increase or decrease is 1 for byte operations, 2 for word operations, and 4 for doubleword operations.
4. Decimals CX without modifying the flags.
5. Checks the zero flag (for SCAS or CMPS) if the REPE or REPNE prefix is used. If the repeat condition holds, loops back to step 1. Otherwise, the loop ends and execution proceeds to the next instruction.

When the repeat loop ends, SI (or DI) points to the position following a match (when using SCAS or CMPS), so you need to decrement or increment DI or SI to point to the element where the last match occurred.

Although string instructions (except LODS) are used most often with repeat prefixes, they can also be used by themselves. In these cases, the SI and/or DI registers are adjusted as specified by the direction flag and the size of operands.

Using String Instructions
To use the 8086-family string instructions, follow the steps outlined in the previous section. Examples in this section illustrate each instruction.

You can also use the techniques in this section with structures and unions, since arrays and strings can be fields in structures and unions. (See the section “Structures and Unions,” following.)

Moving Array Data
The MOVSB instruction copies data from one area of memory to another. To move data, first load the count, source and destination addresses into the appropriate registers. Then use REP with the MOVSB instruction.

```assembly
.MODEL small
.DATA
source BYTE 10 DUP ('0123456789')
destin BYTE 100 DUP (?)
.CODE
mov ax, @data           ; Load same segment
mov ds, ax              ;   to both DS
mov es, ax              ;   and ES

cl d                     ; Work upward
mov cx, LENGTHOF source ; Set iteration count to 100
mov si, OFFSET source   ; Load address of source
mov di, OFFSET destin   ; Load address of destination
rep movsb               ; Move 100 bytes
```

Filling Arrays
The STOS instruction stores a specified value in each position of a string. The string is the destination, so it must be pointed to by ES:DI. The value to store must be in the accumulator.
The next example stores the character ‘a’ in each byte of a 100-byte string, filling the entire string with “aaaa....” Notice how the code stores 50 words rather than
100 bytes. This makes the fill operation faster by reducing the number of iterations. To fill an odd number of bytes, you need to adjust for the last byte.

```assembly
.MODEL small, C
.DATA
destin BYTE 100 DUP (?)
ldestin EQU (LENGTHOF destin) / 2
.CODE
          ; Assume ES = DS
          ; Work upward
        cld
        mov ax, 'aa' ; Load character to fill
        mov cx, ldestin ; Load length of string
        mov di, OFFSET destin ; Load address of destination
        rep stosw ; Store 'aa' into array
```

Comparing Arrays
The **CMPS** instruction compares two strings and points to the address after which a match or nonmatch occurs. If the values are the same, the zero flag is set. Either string can be considered the destination or the source unless a segment override is used. This example using **CMPSB** assumes that the strings are in different segments. Both segments must be initialized to the appropriate segment register.
Listing 5 - Matching Two Strings

```
.MDLM large, C
.DATA
string1 BYTE    "The quick brown fox jumps over the lazy dog"
.FAR
.string2 BYTE    "The quick brown dog jumps over the lazy fox"
Istring EQU     LENGTHOF string2
.CODE
     mov     ax, @data           ; Load data segment
     mov     ds, ax              ;   into DS
     mov     ax, @fardata        ; Load far data segment
     mov     es, ax              ;   into ES
     cld                         ; Work upward
     mov     cx, Istring         ; Load length of string
     mov     si, OFFSET string1  ; Load offset of string1
     mov     di, OFFSET string2  ; Load offset of string2
     repe    cmpsb               ; Compare
     je      allmatch            ; Jump if all match

allmatch:                           ; Special case for all match
```

Loading Data from Arrays

The **LODS** instruction loads a value from a string into the accumulator register. This instruction is not used with a repeat instruction prefix, since continually reloading the accumulator serves no purpose.

The code in this example loads, processes, and displays each byte in a string.
Chapter 5  Defining and Using Complex Data Types  117

.DATA
info  BYTE    0, 1, 2, 3, 4, 5, 6, 7, 8, 9
linfo  WORD    LENGTHOF info

.CODE

cl d                   ; Work upward
mov     cx, linfo       ; Load length
mov     si, OFFSET info ; Load offset of source
mov     ah, 2           ; Display character function

get:
    lodsb                 ; Get a character
    add     al, ‘0’        ; Convert to ASCII
    mov     dl, al         ; Move to DL
    int     21h            ; Call DOS to display character
    loop    get            ; Repeat

Searching Arrays
The SCAS instruction compares the value pointed to by ES:DI with the value in
the accumulator. If both values are the same, it sets the zero flag.

A repeat prefix lets SCAS work on an entire string, scanning (from which SCAS
gets its name) for a particular value called the target. REPNE SCAS sets the
zero flag if it finds the target value in the array. REPE SCAS sets the zero flag
if the scanned array contains nothing but the target value.
This example assumes that ES is not the same as DS and that the address of the string is stored in a pointer variable. The LES instruction loads the far address of the string into ES:DI.

```
.DATA
string BYTE    "The quick brown fox jumps over the lazy dog"
pstring PBYTE    string ; Far pointer to string
lstring EQU     LENGTHOF string ; Length of string

.CODE

cl d                ; Work upward
mov     cx, lstring ; Load length of string
les     di, pstring ; Load address of string
mov     al, 'z'    ; Load character to find
repne   scasb      ; Search
jne     notfound   ; Jump if not found
.es:             ; ES:DI points to character
     ; after first 'z'

notfound:            ; Special case for not found
```

Translating Data in Byte Arrays

The XLAT (Translate) instruction copies a byte from an array of bytes into the AL register. The instruction takes its name from its ability to translate an element’s number into the element itself. For example, given the number 7, XLAT returns byte #7 from the array. The array may hold byte-sized integers or, very often, a table or list of characters. The syntax for XLAT is:

```
XLAT[B] [segment:]memory
```

The optional B suffix (for “byte”) reflects the size of data the instruction handles. Both XLAT and XLATB assemble to exactly the same machine code.

To use XLAT, place the offset of the start of the array in the BX register and the desired index value in AL. Array indexes always begin with 0 in assembly language. To retrieve the first byte of the array, set AL to 0; to retrieve the second byte, set AL to 1, and so forth. XLAT returns the byte element in AL, overwriting the index number.

By default, the DS register contains the segment of the table, but you can use a segment override to specify a different segment. You need not give an operand except when specifying a segment override. (For information about the segment override operator, see “Direct Memory Operands” in Chapter 3.)
This example illustrates **XLAT** by looking up hexadecimal characters in a list. The code converts an eight-bit binary number to a string representing a hexadecimal number.

```
; Table of hexadecimal digits
hex    BYTE    "0123456789ABCDEF"
convert BYTE    "You pressed the key with ASCII code "
key     BYTE    ?, ?, "h", 13, 10, "$"

.CODE

mov     ah, 8               ; Get a key in AL
int     21h                 ; Call DOS
mov     bx, OFFSET hex      ; Load table address
mov     ah, al              ; Save a copy in high byte
and     al, 00001111y       ; Mask out top character
xlat                        ; Translate
mov     key[1], al          ; Store the character
mov     cl, 12              ; Load shift count
shr     ax, cl              ; Shift high char into position
xlat                        ; Translate
mov     key, al             ; Store the character
mov     dx, OFFSET convert  ; Load message
mov     ah, 9               ; Display character
int     21h                 ; Call DOS
```

Although AL cannot contain an index value greater than 255, you can use **XLAT** with arrays containing more than 256 elements. Simply treat each 256-byte block of the array as a smaller sub-array. For example, to retrieve the 260th element of an array, add 256 to BX and set AL=3 (260-256-1).

## Structures and Unions

A structure is a group of possibly dissimilar data types and variables that can be accessed as a unit or by any of its components. The fields within the structure can have different sizes and data types.

Unions are identical to structures, except that the fields of a union overlap in memory, which allows you to define different data formats for the same memory space. Unions can store different types of data depending on the situation. They also can store data as one data type and retrieve it as another data type.

Whereas each field in a structure has an offset relative to the first byte of the structure, all the fields in a union start at the same offset. The size of a structure is the sum of its components; the size of a union is the length of the longest field.
A MASM structure is similar to a `struct` in the C language, a `STRUCTURE` in FORTRAN, and a `RECORD` in Pascal. Unions in MASM are similar to unions in C and FORTRAN, and to variant records in Pascal.

Follow these steps when using structures and unions:

1. Declare a structure (or union) type.
2. Define one or more variables having that type.
3. Reference the fields directly or indirectly with the field (dot) operator.

You can use the entire structure or union variable or just the individual fields as operands in assembler statements. This section explains the allocating, initializing, and nesting of structures and unions.

MASM 6.1 extends the functionality of structures and also makes some changes to MASM 5.1 behavior. If you prefer, you can retain MASM 5.1 behavior by specifying `OPTION OLDSTRUCTS` in your program.

### Declaring Structure and Union Types

When you declare a structure or union type, you create a template for data. The template states the sizes and, optionally, the initial values in the structure or union, but allocates no memory.

The `STRUCT` keyword marks the beginning of a type declaration for a structure. (`STRUCT` and `STRUC` are synonyms.) The format for `STRUCT` and `UNION` type declarations is:

```
name {STRUCT | UNION} [[alignment]] [[NONUNIQUE ]] fielddeclarations
name ENDS
```

The `fielddeclarations` is a series of one or more variable declarations. You can declare default initial values individually or with the `DUP` operator. (See “Defining Structure and Union Variables,” following.) “Referencing Structures, Unions, and Fields,” later in this chapter, explains the `NONUNIQUE` keyword. You can nest structures and unions, as explained in “Nested Structures and Unions,” also later in this chapter.

### Initializing Fields

If you provide initializers for the fields of a structure or union when you declare the type, these initializers become the default value for the fields when you define a variable of that type. “Defining Structure and Union Variables,” following, explains default initializers.
When you initialize the fields of a union type, the type and value of the first field become the default value and type for the union. In this example of an initialized union declaration, the default type for the union is DWORD:

```plaintext
DWB     UNION
   d     DWORD   00FFh
   w     WORD    ?
   b     BYTE    ?
DWB     ENDS
```

If the size of the first member is less than the size of the union, the assembler initializes the rest of the union to zeros. When initializing strings in a type, make sure the initial values are long enough to accommodate the largest possible string.

Field Names

Structure and union field names must be unique within a nesting level because they represent the offset from the beginning of the structure to the corresponding field.

A label elsewhere in the code may have the same name as a structure field, but a text macro cannot. Also, field names between structures need not be unique. Field names must be unique if you place OPTION M510 or OPTION OLDSTRUCTS in your code or use the /Zm option from the command line, since versions of MASM prior to 6.0 require unique field names. (See Appendix A.)

Alignment Value and Offsets for Structures

Data access to structures is faster on aligned fields than on unaligned fields. Therefore, alignment gains speed at the cost of space. Alignment improves access on 16-bit and 32-bit processors but makes no difference in programs executing on an 8-bit 8088 processor.

The way the assembler aligns structure fields determines the amount of space required to store a variable of that type. Each field in a structure has an offset relative to 0. If you specify an alignment in the structure declaration (or with the /Zp command-line option), the offset for each field may be modified by the alignment (or n).

The only values accepted for alignment are 1, 2, and 4. The default is 1. If the type declaration includes an alignment, each field is aligned to either the field’s size or the alignment value, whichever is less. If the field size in bytes is greater than the alignment value, the field is padded so that its offset is evenly divisible by the alignment value. Otherwise, the field is padded so that its offset is evenly divisible by the field size.
Any padding required to reach the correct offset for the field is added prior to allocating the field. The padding consists of zeros and always precedes the aligned field. The size of the structure must also be evenly divisible by the structure alignment value, so zeros may be added at the end of the structure.

If neither the alignment nor the /Zp command-line option is used, the offset is incremented by the size of each data directive. This is the same as a default alignment equal to 1. The alignment specified in the type declaration overrides the /Zp command-line option.

These examples show how the assembler determines offsets:

```asm
STUDENT2 STRUCT 2 ; Alignment value is 2
  score  WORD 1 ; Offset = 0
  id    BYTE 2 ; Offset = 2 (1 byte padding added)
  year  DWORD 3 ; Offset = 4
  sname BYTE 4 ; Offset = 8 (1 byte padding added)
STUDENT2 ENDS
```

One byte of padding is added at the end of the first byte-sized field. Otherwise, the offset of the year field would be 3, which is not divisible by the alignment value of 2. The size of this structure is now 9 bytes. Since 9 is not evenly divisible by 2, 1 byte of padding is added at the end of student2.

```asm
STUDENT4 STRUCT 4 ; Alignment value is 4
  sname BYTE 1 ; Offset = 0 (1 byte padding added)
  score WORD 10 DUP (100) ; Offset = 2
  year BYTE 2 ; Offset = 22 (1 byte padding added so offset of next field is divisible by 4)
  id DWORD 3 ; Offset = 24
STUDENT4 ENDS
```

The alignment value affects the alignment of structure variables, so adding an alignment value affects memory usage. This feature provides compatibility with structures in Microsoft C. MASM 6.1 provides an improved H2INC utility, which C programmers can use to translate C structures to assembly. (See Environment and Tools, Chapter 20.)

The ALIGN, EVEN, and ORG directives can modify how field offsets are placed during structure definition. The EVEN and ALIGN directives insert padding bytes to round the field offset up to the specified alignment boundary. The ORG directive changes the offset of the next field to a given value, either positive or negative. If you use ORG when declaring a structure, you cannot define a structure of that type. ORG is useful when accessing existing data structures, such as a stack frame created by a high-level language.
Defining Structure and Union Variables

Once you have declared a structure or union type, you can define variables of that type. For each variable defined, memory is allocated in the current segment in the format declared by the type. The syntax for defining a structure or union variable is:

\[
\text{name} \text{ typename} < \text{initializer} \ldots > \\
\text{name} \text{ typename} \{ \text{initializer} \ldots \} \\
\text{name} \text{ typename constant DUP} \{ \text{initializer} \ldots \}
\]

The \text{name} is the label assigned to the variable. If you do not provide a name, the assembler allocates space for the variable but does not give it a symbolic name. The \text{typename} is the name of a previously declared structure or union type.

You can give an \text{initializer} for each field. Each initializer must correspond in type with the field defined in the type declaration. For unions, the type of the initializer must be the same as the type for the first field. An initialization list can also use the \text{DUP} operator.

The list of initializers can be broken only after a comma unless you end the line with a continuation character (\). The last curly brace or angle bracket must appear on the same line as the last initializer. You can also use the line continuation character to extend a line as shown in the \text{ITEMS} declaration that follows. Angle brackets and curly braces can be intermixed in an initialization as long as they match. This example illustrates the options for initializing lists in structures of type \text{ITEMS}:
ITEMS       STRUCT
    Iname     BYTE      'Item Name'
    Inum      WORD      ?
UNION      ITYPE                ; UNION keyword appears first
    oldtype BYTE      0          ; when nested in structure.
    newtype WORD      ?          ; (See "Nested Structures
ENDS                           ; and Unions," following ).
ITEMS       ENDS

.DATA
Item1   ITEMS   <>              ; Accepts default initializers
Item2   ITEMS   {}              ; Accepts default initializers
Item3   ITEMS   <'Bolts', 126>   ; Overrides default value of first
;   2 fields; use default of
;   the third field
Item4   ITEMS   {\n        'Bolts', ; Item name
           126 \ ; Part number
    }

The example defines—that is, allocates space for—four structures of the
ITEMS type. The structures are named Item1 through Item4. Each definition
requires the angle brackets or curly braces even when not initialized. If you
initialize more than one field, separate the values with commas, as shown in
Item3 and Item4.

You need not initialize all fields in a structure. If a field is blank, the assembler
uses the structure’s initial value given for that field in the declaration. If there is
no default value, the field value is left unspecified.

For nested structures or unions, however, these are equivalent:

Item5   ITEMS   {'Bolts', ,     }
Item6   ITEMS   {'Bolts', , { } }

A variable and an array of union type WB look like this:
Arrays as Field Initializers

The size of the initializer determines the length of the array that can override the contents of a field in a variable definition. The override cannot contain more elements than the default. Specifying fewer override array elements changes the first $n$ values of the default where $n$ is the number of values in the override. The rest of the array elements take their default values from the initializer.

Strings as Field Initializers

If the override is shorter, the assembler pads the override with spaces to equal the length of the initializer. If the initializer is a string and the override value is not a string, the override value must be enclosed in angle brackets or curly braces.

A string can override any member of type \texttt{BYTE} (or \texttt{SBYTE}). You need not enclose the string in angle brackets or curly braces unless mixed with other override methods.

If a structure has an initialized string field or an array of bytes, any new string assigned to a variable of the field that is smaller than the default is padded with spaces. The assembler adds four spaces at the end of 'Bolts' in the variables of type \texttt{ITEMS} previously shown. The \texttt{Iname} field in the \texttt{ITEMS} structure cannot contain a field initializer longer than 'Item Name'.

Structures as Field Initializers

Initializers for structure variables must be enclosed in curly braces or angle brackets, but you can specify overrides with fewer elements than the defaults.

This example illustrates the use of default values with structures as field initializers:
DI SKDRI VES STRUCT
   a1    BYTE ?
   b1    BYTE ?
   c1    BYTE ?
DI SKDRI VES ENDS

INFO STRUCT
   buffer BYTE 100 DUP (?)
   crlf  BYTE 13, 10
   query BYTE 'Filename: ' ; String <= can override
   endmark BYTE 36
   drives DISKDRIVES <0, 1, 1>
INFO ENDS

info1 INFO { , , 'Dir' }

; Next line illegal since name in query field is too long:
; info2 INFO {"TESTFILE", , "DirectoryName"}

lotsof INFO { , , 'file1', , {0,0,0} },
             { , , 'file2', , {0,0,1} },
             { , , 'file3', , {0,0,2} }

The following diagram shows how the assembler stores info1.

The initialization for drives gives default values for all three fields of the structure. The fields left blank in info1 use the default values for those fields. The info2 declaration is illegal because "DirectoryName" is longer than the initial string for that field.

Arrays of Structures and Unions
You can define an array of structures using the DUP operator (see “Declaring and Referencing Arrays,” earlier in this chapter) or by creating a list of structures. For example, you can define an array of structure variables like this:
Item7 ITEMS 30 DUP (), (10)

The Item7 array defined here has 30 elements of type ITEMS, with the third field of each element (the union) initialized to 10.

You can also list array elements as shown in the following example.

Item8 ITEMS {'Bolts', 126, 10},
{'Pliers', 139, 10},
{'Saws', 414, 10}

Redeclaring a Structure

The assembler generates an error when you declare a structure more than once unless the following are the same:

- Field names
- Offsets of named fields
- Initialization lists
- Field alignment value

LENGTHOF, SIZEOF, and TYPE for Structures

The size of a structure determined by SIZEOF is the offset of the last field, plus the size of the last field, plus any padding required for proper alignment. (For information about alignment, see “Declaring Structure and Union Types,” earlier in this chapter.)
This example, using the preceding data declarations, shows how to use the `LENGTHOF`, `SIZEOF`, and `TYPE` operators with structures.

```plaintext
INFO            STRUCT
  buffer        BYTE    100 DUP (?)
  crlf          BYTE    13, 10
  query         BYTE    'Filename: '
  endmark       BYTE    36
  drives        DISKDRIVES <0, 1, 1>
INFO            ENDS

info1   INFO    { , , 'Dir' }
lotsof INFO    { , , 'file1', , {0,0,0} },
               { , , 'file2', , {0,0,1} },
               { , , 'file3', , {0,0,2} }

sinfo1 EQU     SIZEOF    info1  ; 116 = number of bytes in
; initializers
linfo1 EQU     LENGTHOF  info1  ; 1 = number of items
tinfo1 EQU     TYPE      info1  ; 116 = same as size

slotsof EQU     SIZEOF    lotsof ; 116 * 3 = number of bytes in
; initializers
llotsof EQU     LENGTHOF  lotsof ; 3 = number of items
tlotsof EQU     TYPE      lotsof ; 116 = same as size for structure
; of type INFO
```

**LENGTHOF, SIZEOF, and TYPE for Unions**

The size of a union determined by `SIZEOF` is the size of the longest field plus any padding required. The length of a union variable determined by `LENGTHOF` equals the number of initializers defined inside angle brackets or curly braces. `TYPE` returns a value indicating the type of the longest field.

```plaintext
DWB     UNION
  d     DWORD   ?
  w     WORD    ?
  b     BYTE    ?
DWB     ENDS

num     DWB     {0FFFFh}
array   DWB     (100 / SIZEOF DWB) DUP ({0})

snum    EQU     SIZEOF   num      ; = 4
lnum    EQU     LENGTHOF num      ; = 1
tnum    EQU     TYPE      num      ; = 4
sarray  EQU     SIZEOF   array    ; = 100 (4*25)
larray  EQU     LENGTHOF array    ; = 25
tarray  EQU     TYPE      array    ; = 4
```
Referencing Structures, Unions, and Fields

Like other variables, structure variables can be accessed by name. You can access fields within structure variables with this syntax:

\textit{variable. field}

References to fields must always be fully qualified, with the structure or union names and the dot operator preceding the field name. The assembler requires that you use the dot operator only with structure fields, not as an alternative to the plus operator; nor can you use the plus operator as an alternative to the dot operator.

The following example shows several ways to reference the fields of a structure of type \texttt{DATE}.

\begin{verbatim}
DATE    STRUCT                            ; Defines structure type
    month BYTE    ?
    day   BYTE    ?
    year  WORD    ?
DATE    ENDS

yesterday       DATE    {1, 20, 1993}     ; Declare structure variable.

mov     al, yesterday.day         ; Use structure variables
mov     bx, OFFSET yesterday      ; Load structure address
mov     al, (DATE PTR [bx]).month ; Use as indirect operand
mov     al, [bx].date.month       ; This is necessary only if
    ; month is already a
    ; field in a different
    ; structure

Under \texttt{OPTION M510} or \texttt{OPTION OLDSTRUCTS}, unique structure names do not need to be qualified. However, if the \texttt{NONUNIQUE} keyword appears in a structure definition, all fields of the structure must be fully qualified when referenced, even if the \texttt{OPTION OLDSTRUCTS} directive appears in the code. Also, you must qualify all references to a field. (For information on the \texttt{OPTION} directive, see Chapter 1.)

Even if the initialized union is the size of a \texttt{WORD} or \texttt{DWORD}, members of structures or unions are accessible only through the field’s names.
In the following example, the two `MOV` statements show how you can access the elements of an array of unions.

```assembly
WB UNION
  w WORD    ?
  b BYTE    ?
WB ENDS

array WB (100 / SIZEOF WB) DUP ({0})

mov array[12].w, 40h
mov array[32].b, 2
```

As the preceding code illustrates, you can use unions to access the same data in more than one form. One application of structures and unions is to simplify the task of reinitializing a far pointer. For a far pointer declared as

```assembly
FPWORD TYPEDEF FAR PTR WORD

.DATA
WordPtr FPWORD ?
```

you must follow these steps to point `WordPtr` to a word value named `ThisWord` in the current data segment.

```assembly
mov WORD PTR WordPtr[2], ds
mov WORD PTR WordPtr, OFFSET ThisWord
```

The preceding method requires that you remember whether the segment or the offset is stored first. However, if your program declares a union like this:

```assembly
uptr UNION
dwptr FPWORD 0
STRUCT
  offs WORD 0
  segm WORD 0
ENDS
uptr ENDS
```
You can initialize a far pointer with these steps:

```assembly
.DATA
WdPtr2 uptr <>
.
.
.
    mov WdPtr2.segm, ds
    mov WdPtr2.offs, OFFSET ThisWord
```

This code moves the segment and the offset into the pointer and then moves the pointer into a register with the other field of the union. Although this technique does not reduce the code size, it avoids confusion about the order for loading the segment and offset.

### Nested Structures and Unions

You can nest structures and unions in several ways. This section explains how to refer to the fields in a nested structure or union. The following example illustrates the four techniques for nesting, and how to reference the fields. Note the syntax for nested structures. The techniques are reviewed following the example.

```assembly
ITEMS          STRUCT
    Inum          WORD    ?
    Iname         BYTE    'Item Name'
ITEMS          ENDS

INVENTORY      STRUCT
    UpDate        WORD    ?
    oldItem       ITEMS   { 
        100,
        'AF8' \   ; Named variable of
            ;   existing structure
    IITEMS   { ?, '94C' } ; Unnamed variable of
            ;   existing type
    STRUCT ups                          ; Named nested structure
        source      WORD    ?
        shipmode    BYTE    ?
    ENDS
    STRUCT                              ; Unnamed nested structure
        f1          WORD    ?
        f2          WORD    ?
    ENDS
INVENTORY      ENDS
```

```assembly
.DATA
yearly INVENTORY { }
```
; Referencing each type of data in the yearly structure:

```
mov    ax, yearly.oldItem.Inum
mov    yearly.ups.shipmode, 'A'
mov    yearly.Inum, 'C'
mov    ax, yearly.f1
```

To nest structures and unions, you can use any of these techniques:

- The field of a structure or union can be a named variable of an existing structure or union type, as in the `oldItem` field. Because `INVENTORY` contains two structures of type `ITEMS`, the field names in `oldItem` are not unique. Therefore, you must use the full field names when referencing those fields, as in the statement:

```
mov    ax, yearly.oldItem.Inum
```

- To declare a named structure or union inside another structure or union, give the `STRUCT` or `UNION` keyword first and then define a label for it. Fields of the nested structure or union must always be qualified:

```
mov    yearly.ups.shipmode, 'A'
```

- As shown in the `Items` field of `Inventory`, you also can use unnamed variables of existing structures or unions inside another structure or union. In these cases, you can reference fields directly:

```
mov    yearly.Inum, 'C'
mov    ax, yearly.f1
```

### Records

Records are similar to structures, except that fields in records are bit strings. Each bit field in a record variable can be used separately in constant operands or expressions. The processor cannot access bits individually at run time, but it can access bit fields with instructions that manipulate bits.

Records are bytes, words, or doublewords in which the individual bits or groups of bits are considered fields. In general, the three steps for using record variables are the same as those for using other complex data types:

1. Declare a record type.
2. Define one or more variables having the record type.
3. Reference record variables using shifts and masks.

Once it is defined, you can use the record variable as an operand in assembler statements.
This section explains the record declaration syntax and the use of the MASK and WIDTH operators. It also shows some applications of record variables and constants.

### Declaring Record Types

A record type creates a template for data with the sizes and, optionally, the initial values for bit fields in the record. It does not allocate memory space for the record.

The RECORD directive declares a record type for an 8-bit, 16-bit, or 32-bit record that contains one or more bit fields. The maximum size is based on the expression word size. See OPTION EXPR16 and OPTION EXPR32 in Chapter 1. The syntax is:

```
recordname RECORD field [[, field]]...
```

The **field** declares the name, width, and initial value for the field. The syntax for each **field** is:

```
fieldname:width [[=expression]]
```

Global labels, macro names, and record field names must all be unique, but record field names can have the same names as structure field names. **Width** is the number of bits in the field, and **expression** is a constant giving the initial (or default) value for the field. Record definitions can span more than one line if the continued lines end with commas.

If **expression** is given, it declares the initial value for the field. The assembler generates an error message if an initial value is too large for the width of its field.

The first field in the declaration always goes into the most significant bits of the record. Subsequent fields are placed to the right in the succeeding bits. If the fields do not total exactly 8, 16, or 32 bits as appropriate, the entire record is shifted right, so the last bit of the last field is the lowest bit of the record. Unused bits in the high end of the record are initialized to 0.

The following example creates a byte record type **COLOR** having four fields: **blink**, **back**, **intense**, and **fore**. The contents of the record type are shown after the example. Since no initial values are given, all bits are set to 0. Note that this is only a template maintained by the assembler. It allocates no space in the data segment.
The next example creates a record type CW that has six fields. Each record declared with this type occupies 16 bits of memory. Initial (default) values are given for each field. You can use them when declaring data for the record. The bit diagram after the example shows the contents of the record type.

```
COLOR RECORD blink:1, back:3, intense:1, fore:3
```

```
The record name is the name of a record type previously declared with the RECORD directive.

A fieldlist for each field in the record can be a list of integers, character constants, or expressions that correspond to a value compatible with the size of the field. You must include curly braces or angle brackets even when you do not specify an initial value.

If you use the DUP operator (see “Declaring and Referencing Arrays,” earlier in this chapter) to initialize multiple record variables, only the angle brackets and
any initial values need to be enclosed in parentheses. For example, you can define an array of record variables with

\[
\text{xmas COLOR 50 DUP ( <1, 2, 0, 4> )}
\]

You do not have to initialize all fields in a record. If an initial value is blank, the assembler automatically stores the default initial value of the field. If there is no default value, the assembler clears each bit in the field.

The definition in the following example creates a variable named \text{warning} whose type is given by the record type \text{COLOR}. The initial values of the fields in the variable are set to the values given in the record definition. The initial values override any default record values given in the declaration.

\[
\begin{align*}
\text{COLOR RECORD} & \quad \text{blink: 1, back: 3, intense: 1, fore: 3} \quad \text{Record} \\
\text{warning COLOR} & \quad <1, 0, 1, 4> \quad \text{Record definition}
\end{align*}
\]

\textbf{LENGTHOF, SIZEOF, and TYPE with Records}

The \text{SIZEOF} and \text{TYPE} operators applied to a record name return the number of bytes used by the record. \text{SIZEOF} returns the number of bytes a record variable occupies. You cannot use \text{LENGTHOF} with a record declaration, but you can use it with defined record variables. \text{LENGTHOF} returns the number of records in an array of records, or 1 for a single record variable. The following example illustrates these points.

\[
\begin{align*}
\text{RGBCOLOR RECORD red: 3, green: 3, blue: 3} & \\
\text{mov ax, RGBCOLOR} & \quad \text{Equivalent to "mov ax, 01FFh"} \\
\text{mov ax, LENGTHOF RGBCOLOR} & \quad \text{Illegal since \text{LENGTHOF} can only apply to data label} \\
\text{mov ax, SIZEOF RGBCOLOR} & \quad \text{Equivalent to "mov ax, 2"} \\
\text{mov ax, TYPE RGBCOLOR} & \quad \text{Equivalent to "mov ax, 2"}
\end{align*}
\]
; Record instance
; 8 bits stored in 1 byte
RGBCOLOR2   RECORD red:3, green:3, blue:2
rgb         RGBCOLOR2 <1, 1, 1> ; Initialize to 00100101y

mov ax, RGBCOLOR2 ; Equivalent to
;   "mov ax, 00FFh"
mov ax, LENGTHOF rgb ; Equivalent to "mov ax, 1"
mov ax, SI ZEOF rgb ; Equivalent to "mov ax, 1"
mov ax, TYPE rgb ; Equivalent to "mov ax, 1"

Record Operators

The WIDTH operator (used only with records) returns the width in bits of a record or record field. The MASK operator returns a bit mask for the bit positions occupied by the given record field. A bit in the mask contains a 1 if that bit corresponds to a bit field. The following example shows how to use MASK and WIDTH.

.DAT
COLOR       RECORD blink:1, back:3, intense:1, fore:3
message     COLOR <1, 5, 1, 1>
wblink     EQU WIDTH blink ; "wblink" = 1
wback      EQU WIDTH back ; "wback" = 3
wintens    EQU WIDTH intense ; "wintens" = 1
wfore       EQU WIDTH fore ; "wfore" = 3
wcolor      EQU WIDTH COLOR ; "wcolor" = 8

.CODE

mov ah, message ; Load initial 1101 1001
and ah, NOT MASK back ; Turn off AND 1000 1111
; "back" 1000 0001
or ah, MASK blink ; Turn on OR 1000 0000
; "blink" 1000 1001
xor ah, MASK intense ; Toggle XOR 0000 1000
; "intense" 1000 0001

IF (WIDTH COLOR) GT 8 ; If color is 16 bit, load
mov ax, message ; into 16-bit register
ELSE
mov al, message ; load into low 8-bit register
xor ah, ah ; and clear high 8-bits
ENDIF
The example continues by illustrating several ways in which record fields can serve as operands and expressions:

; Rotate "back" of "message" without changing other values

    mov     al, message      ; Load value from memory
    mov     ah, al           ; Save a copy for work      1101 1001=ah/al
    and     al, NOT MASK back; Mask out old bits     AND 1000 1111=mask
    ; to save old message       ---------
    ;                           1000 1001=al
    mov     cl, back         ; Load bit position
    shr     ah, cl           ; Shift to right            0000 1101=ah
    inc     ah               ; Increment                 0000 1110=ah
    shl     ah, cl           ; Shift left again          1110 0000=ah
    and     ah, MASK back    ; Mask off extra bits   AND 0111 0000=mask
    ; to get new message       ---------
    ;                           0110 0000 ah
    or      ah, al           ; Combine old and new OR 1000 1001 al
    ;                         ---------
    mov     message, ah      ; Write back to memory      1110 1001 ah

Record variables are often used with the logical operators to perform logical operations on the bit fields of the record, as in the previous example using the **MASK** operator.
CHAPTER 6

Using Floating-Point and Binary Coded Decimal Numbers

MASM requires different techniques for handling floating-point (real) numbers and binary coded decimal (BCD) numbers than for handling integers. You have two choices for working with real numbers—a math coprocessor or emulation routines.

Math coprocessors—the 8087, 80287, and 80387 chips—work with the main processor to handle real-number calculations. The 80486 processor performs floating-point operations directly. All information in this chapter pertaining to the 80387 coprocessor applies to the 80486DX processor as well. It does not apply to the 80486SX, which does not provide an on-chip coprocessor.

This chapter begins with a summary of the directives and formats of floating-point data that you need to allocate memory storage and initialize variables before you can work with floating-point numbers.

The chapter then explains how to use a math coprocessor for floating-point operations. It covers:

- The architecture of the registers.
- The operands for the coprocessor instruction formats.
- The coordination of coprocessor and main processor memory access.
- The basic groups of coprocessor instructions—for loading and storing data, doing arithmetic calculations, and controlling program flow.

The next main section describes emulation libraries. The emulation routines provided with all Microsoft high-level languages enable you to use coprocessor instructions as though your computer had a math coprocessor. However, some coprocessor instructions are not handled by emulation, as this section explains.

Finally, because math coprocessor and emulation routines can also operate on BCD numbers, this chapter includes the instruction set for these numbers.
Using Floating-Point Numbers

Before using floating-point data in your program, you need to allocate the memory storage for the data. You can then initialize variables either as real numbers in decimal form or as encoded hexadecimals. The assembler stores allocated data in 10-byte IEEE format. This section covers floating-point declarations and floating-point data formats.

Declaring Floating-Point Variables and Constants

You can allocate real constants using the REAL4, REAL8, and REAL10 directives. These directives allocate the following floating-point numbers:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Size</th>
</tr>
</thead>
<tbody>
<tr>
<td>REAL4</td>
<td>Short (32-bit) real numbers</td>
</tr>
<tr>
<td>REAL8</td>
<td>Long (64-bit) real numbers</td>
</tr>
<tr>
<td>REAL10</td>
<td>10-byte (80-bit) real numbers and BCD numbers</td>
</tr>
</tbody>
</table>

Table 6.1 lists the possible ranges for floating-point variables. The number of significant digits can vary in an arithmetic operation as the least-significant digit may be lost through rounding errors. This occurs regularly for short and long real numbers, so you should assume the lesser value of significant digits shown in Table 6.1. Ten-byte real numbers are much less susceptible to rounding errors for reasons described in the next section. However, under certain circumstances, 10-byte real operations can have a precision of only 18 digits.

<table>
<thead>
<tr>
<th>Data Type</th>
<th>Bits</th>
<th>Significant Digits</th>
<th>Approximate Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>Short real</td>
<td>32</td>
<td>6–7</td>
<td>1.18 x 10^-38 to 3.40 x 10^38</td>
</tr>
<tr>
<td>Long real</td>
<td>64</td>
<td>15–16</td>
<td>2.23 x 10^-308 to 1.79 x 10^308</td>
</tr>
<tr>
<td>10-byte real</td>
<td>80</td>
<td>19</td>
<td>3.37 x 10^-4932 to 1.18 x 10^4932</td>
</tr>
</tbody>
</table>

With versions of MASM prior to 6.0, the DD, DQ, and DT directives could allocate real constants. MASM 6.1 still supports these directives, but the variables are integers rather than floating-point values. Although this makes no difference in the assembly code, CodeView displays the values incorrectly.

You can specify floating-point constants either as decimal constants or as encoded hexadecimal constants. You can express decimal real-number constants in the form:

```
[[+ | –]] integer[[fraction]][E[+ | –]exponent]
```
For example, the numbers 2.523E1 and -3.6E-2 are written in the correct decimal format. You can use these numbers as initializers for real-number variables.

The assembler always evaluates digits of real numbers as base 10. It converts real-number constants given in decimal format to a binary format. The sign, exponent, and decimal part of the real number are encoded as bit fields within the number.

You can also specify the encoded format directly with hexadecimal digits (0–9 plus A–F). The number must begin with a decimal digit (0–9) and end with the real-number designator (R). It cannot be signed. For example, the hexadecimal number 3F800000r can serve as an initializer for a doubleword-sized variable.

The maximum range of exponent values and the number of digits required in the hexadecimal number depend on the directive. The number of digits for encoded numbers used with REAL4, REAL8, and REAL10 must be 8, 16, and 20 digits, respectively. If the number has a leading zero, the number must be 9, 17, or 21 digits.

Examples of decimal constant and hexadecimal specifications are shown here:

; Real numbers
short REAL4 25.23 ; IEEE format
double REAL8 2.523E1 ; IEEE format
tenbyte REAL10 2523.0E-2 ; 10-byte real format

; Encoded as hexadecimal
ieeshort REAL4 3F800000r ; 1.0 as IEEE short
ieeedouble REAL8 3FF0000000000000r ; 1.0 as IEEE long
temporary REAL10 3FFFF800000000000000r ; 1.0 as 10-byte
       ; real

The section “Storing Numbers in Floating-Point Format,” following, explains the IEEE formats—the way the assembler actually stores the data.

Pascal or C programmers may prefer to create language-specific typedef declarations, as illustrated in this example:
; C-language specific
float TYPEDEF REAL4
double TYPEDEF REAL8
long_double TYPEDEF REAL10
; Pascal-language specific
SINGLE TYPEDEF REAL4
DOUBLE TYPEDEF REAL8
EXTENDED TYPEDEF REAL10

For applications of **TYPEDEF**, see “Defining Pointer Types with TYPEDEF,” page 75.

### Storing Numbers in Floating-Point Format

The assembler stores floating-point variables in the IEEE format. MASM 6.1 does not support `.MSFLOAT` and Microsoft binary format, which are available in version 5.1 and earlier. Figure 6.1 illustrates the IEEE format for encoding short (4-byte), long (8-byte), and 10-byte real numbers. Although this figure places the most significant bit first for illustration, low bytes actually appear first in memory.
The following list explains how the parts of a real number are stored in the IEEE format. Each item in the list refers to an item in Figure 6.1.

- Sign bit (0 for positive or 1 for negative) in the upper bit of the first byte.
- Exponent in the next bits in sequence (8 bits for a short real number, 11 bits for a long real number, and 15 bits for a 10-byte real number).
The integer part of the significand in bit 63 for the 10-byte real format. By absorbing carry values, this bit allows 10-byte real operations to preserve precision to 19 digits. The integer part is always 1 in short and long real numbers; consequently, these formats do not provide a bit for the integer, since there is no point in storing it.

Decimal part of the significand in the remaining bits. The length is 23 bits for short real numbers, 52 bits for long real numbers, and 63 bits for 10-byte real numbers.

The exponent field represents a multiplier $2^n$. To accommodate negative exponents (such as $2^{-6}$), the value in the exponent field is biased; that is, the actual exponent is determined by subtracting the appropriate bias value from the value in the exponent field. For example, the bias for short real numbers is 127. If the value in the exponent field is 130, the exponent represents a value of $2^{130-127}$, or $2^3$. The bias for long real numbers is 1,023. The bias for 10-byte real numbers is 16,383.

Once you have declared floating-point data for your program, you can use coprocessor or emulator instructions to access the data. The next section focuses on the coprocessor architecture, instructions, and operands required for floating-point operations.

### Using a Math Coprocessor

When used with real numbers, packed BCD numbers, or long integers, coprocessors (the 8087, 80287, 80387, and 80486) calculate many times faster than the 8086-based processors. The coprocessor handles data with its own registers. The organization of these registers can be one of the four formats for using operands explained in “Instruction and Operand Formats,” later in this section.

This section describes how the coprocessor transfers data to and from the coprocessor, coordinates processor and coprocessor operations, and controls program flow.
Coprocessor Architecture

The coprocessor accesses memory as the CPU does, but it has its own data and control registers—eight data registers organized as a stack and seven control registers similar to the 8086 flag registers. The coprocessor’s instruction set provides direct access to these registers.

The eight 80-bit data registers of the 8087-based coprocessors are organized as a stack, although they need not be used as a stack. As data items are pushed into the top register, previous data items move into higher-numbered registers, which are lower on the stack. Register 0 is the top of the stack; register 7 is the bottom. The syntax for specifying registers is:

\[ \text{ST}[(\text{number})] \]

The \textit{number} must be a digit between 0 and 7 or a constant expression that evaluates to a number from 0 to 7. \textit{ST} is another way to refer to \textit{ST}(0).

All coprocessor data is stored in registers in the 10-byte real format. The registers and the register format are shown in Figure 6.2.

![Figure 6.2 Coprocessor Data Registers](image)

Internally, all calculations are done on numbers of the same type. Since 10-byte real numbers have the greatest precision, lower-precision numbers are guaranteed not to lose precision as a result of calculations. The instructions that transfer values between the main memory and the coprocessor automatically convert numbers to and from the 10-byte real format.
Instruction and Operand Formats

Because of the stack organization of registers, you can consider registers either as elements on a stack or as registers much like 8086-family registers. Table 6.2 lists the four main groups of coprocessor instructions and the general syntax for each. The names given to the instruction format reflect the way the instruction uses the coprocessor registers. The instruction operands are placed in the coprocessor data registers before the instruction executes.

Table 6.2 Coprocessor Operand Formats

<table>
<thead>
<tr>
<th>Instruction Format</th>
<th>Syntax</th>
<th>Implied Operands</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Classical stack</td>
<td>Finstruction</td>
<td>ST, ST(1)</td>
<td>f add</td>
</tr>
<tr>
<td>Memory</td>
<td>Finstruction memory</td>
<td>ST</td>
<td>f add memloc</td>
</tr>
<tr>
<td>Register</td>
<td>Finstruction ST(num), ST</td>
<td>—</td>
<td>f add st(5), st</td>
</tr>
<tr>
<td></td>
<td>Finstruction ST, ST(num)</td>
<td>—</td>
<td>f add st, st(3)</td>
</tr>
<tr>
<td>Register pop</td>
<td>FinstructionP ST(num), ST</td>
<td>—</td>
<td>f addp st(4), st</td>
</tr>
</tbody>
</table>

You can easily recognize coprocessor instructions because, unlike all 8086-family instruction mnemonics, they start with the letter F. Coprocessor instructions can never have immediate operands and, with the exception of the FSTSW instruction, they cannot have processor registers as operands.

Classical-Stack Format

Instructions in the classical-stack format treat the coprocessor registers like items on a stack—thus its name. Items are pushed onto or popped off the top elements of the stack. Since only the top item can be accessed on a traditional stack, there is no need to specify operands. The first (top) register (and the second, if the instruction needs two operands) is always assumed.

ST (the top of the stack) is the source operand in coprocessor arithmetic operations. ST(1), the second register, is the destination. The result of the operation replaces the destination operand, and the source is popped off the stack. This leaves the result at the top of the stack.
The following example illustrates the classical-stack format; Figure 6.3 shows the status of the register stack after each instruction.

```
fld1               ; Push 1 into first position
fldpi              ; Push pi into first position
fadd               ; Add pi and 1 and pop
```

![Figure 6.3](image)

**Figure 6.3  Status of the Register Stack**

**Memory Format**

Instructions that use the memory format, such as data transfer instructions, also treat coprocessor registers like items on a stack. However, with this format, items are pushed from memory onto the top element of the stack, or popped from the top element to memory. You must specify the memory operand.

Some instructions that use the memory format specify how a memory operand is to be interpreted— as an integer (I) or as a binary coded decimal (B). The letter I or B follows the initial F in the syntax. For example, FILD interprets its operand as an integer and FBLD interprets its operand as a BCD number. If the instruction name does not include a type letter, the instruction works on real numbers.

You can also use memory operands in calculation instructions that operate on two values (see “Using Coprocessor Instructions,” later in this section). The memory operand is always the source. The stack top (ST) is always the implied destination.
The result of the operation replaces the destination without changing its stack position, as shown in this example and in Figure 6.4:

```
.DAT
m1       REAL4  1.0
m2       REAL4  2.0

.CODE

fld    m1      ; Push m1 into first position
fld    m2      ; Push m2 into first position
fadd   m1      ; Add m2 to first position
fstp   m1      ; Pop first position into m1
fst    m2      ; Copy first position to m2
```

![Figure 6.4](image)

**Figure 6.4  Status of the Register Stack and Memory Locations**

**Register Format**

Instructions that use the register format treat coprocessor registers as registers rather than as stack elements. Instructions that use this format require two register operands; one of them must be the stack top (ST).

In the register format, specify all operands by name. The first operand is the destination; its value is replaced with the result of the operation. The second operand is the source; it is not affected by the operation. The stack positions of the operands do not change.
The only instructions that use the register operand format are the **FXCH** instruction and arithmetic instructions for calculations on two values. With the **FXCH** instruction, the stack top is implied and need not be specified, as shown in this example and in Figure 6.5:

\[
\begin{align*}
  \text{fadd} & \quad \text{st(1), st} \quad \text{Add second position to first} - \\
  & \quad \text{result goes in second position} \\
  \text{fadd} & \quad \text{st, st(2)} \quad \text{Add first position to third} - \\
  & \quad \text{result goes in first position} \\
  \text{fxch} & \quad \text{st(1)} \quad \text{Exchange first and second positions}
\end{align*}
\]

![Figure 6.5 Status of the Previously Initialized Register Stack](image)

**Register-Pop Format**

The register-pop format treats coprocessor registers as a modified stack. The source register must always be the stack top. Specify the destination with the register's name.

Instructions with this format place the result of the operation into the destination operand, and the top pops off the stack. The register-pop format is used only for instructions for calculations on two values, as in this example and in Figure 6.6:

\[
\begin{align*}
  \text{faddp} & \quad \text{st(2), st} \quad \text{Add first and third positions and pop} - \\
  & \quad \text{first position destroyed;} \\
  & \quad \text{first moves to second and holds result}
\end{align*}
\]
Coordinating Memory Access

The math coprocessor and main processor work simultaneously. However, since the coprocessor cannot handle device input or output, data originates in the main processor.

The main processor and the coprocessor have their own registers, which are separate and inaccessible to each other. They exchange data through memory, since memory is available to both.

When using the coprocessor, follow these three steps:

1. Load data from memory to coprocessor registers.
2. Process the data.
3. Store the data from coprocessor registers back to memory.

Step 2, processing the data, can occur while the main processor is handling other tasks. Steps 1 and 3 must be coordinated with the main processor so that the processor and coprocessor do not try to access the same memory at the same time; otherwise, problems of coordinating memory access can occur. Since the processor and coprocessor work independently, they may not finish working on memory in the order in which you give instructions. The two potential timing conflicts that can occur are handled in different ways.

One timing conflict results from a coprocessor instruction following a processor instruction. The processor may have to wait until the coprocessor finishes if the next processor instruction requires the result of the coprocessor’s calculation. You do not have to write your code to avoid this conflict, however. The assembler coordinates this timing automatically for the 8088 and 8086 processors, and the processor coordinates it automatically on the 80186–80486 processors. This is the case shown in the first example that follows.

Another conflict results from a processor instruction that accesses memory following a coprocessor instruction that accesses the same memory. The processor can try to load a variable that is still being used by the coprocessor. You need careful synchronization to control the timing, and this synchronization is not automatic on the 8087 coprocessor. For code to run correctly on the 8087, you must include WAIT or FWAIT (mnemonics for the same instruction) to ensure that the coprocessor finishes before the processor begins, as shown in the second example.
In this situation, the processor does not generate the `FWAIT` instruction automatically.

; Processor instruction first - No wait needed
mov WORD PTR mem32[0], ax ; Load memory
mov WORD PTR mem32[2], dx
fld mem82                   ; Load to register

; Coprocessor instruction first - Wait needed (for 8087)
fist mem82                   ; Store to memory
fwait                        ; Wait until coprocessor is done
mov ax, WORD PTR mem32[0]   ; Move to register
mov dx, WORD PTR mem32[2]

When generating code for the 8087 coprocessor, the assembler automatically inserts a `WAIT` instruction before the coprocessor instruction. However, if you use the `.286` or `.386` directive, the compiler assumes that the coprocessor instructions are for the 80287 or 80387 and does not insert the `WAIT` instruction. If your code does not need to run on an 8086 or 8088 processor, you can make your programs smaller and more efficient by using the `.286` or `.386` directive.

**Using Coprocessor Instructions**

The 8087 family of coprocessors has separate instructions for each of the following operations:

- Loading and storing data
- Doing arithmetic calculations
- Controlling program flow

The following sections explain the available instructions and show how to use them for each of these operations. For general syntax information, see “Instruction and Operand Formats,” earlier in this section.

**Loading and Storing Data**

Data-transfer instructions copy data between main memory and the coprocessor registers or between different coprocessor registers. Two principles govern data transfers:

- The choice of instruction determines whether a value in memory is considered an integer, a BCD number, or a real number. The value is always considered a 10-byte real number once transferred to the coprocessor.
The size of the operand determines the size of a value in memory. Values in the coprocessor always take up 10 bytes.

You can transfer data to stack registers using load commands. These commands push data onto the stack from memory or from coprocessor registers. Store commands remove data. Some store commands pop data off the register stack into memory or coprocessor registers; others simply copy the data without changing it on the stack.

If you use constants as operands, you cannot load them directly into coprocessor registers. You must allocate memory and initialize a variable to a constant value. That variable can then be loaded by using one of the load instructions in the following list.

The math coprocessor offers a few special instructions for loading certain constants. You can load 0, 1, pi, and several common logarithmic values directly. Using these instructions is faster and often more precise than loading the values from initialized variables.

All instructions that load constants have the stack top as the implied destination operand. The constant to be loaded is the implied source operand.

The coprocessor data area, or parts of it, can also be moved to memory and later loaded back. You may want to do this to save the current state of the coprocessor before executing a procedure. After the procedure ends, restore the previous status. Saving coprocessor data is also useful when you want to modify coprocessor behavior by writing certain data to main memory, operating on the data with 8086-family instructions, and then loading it back to the coprocessor data area.

Use the following instructions for transferring numbers to and from registers:

<table>
<thead>
<tr>
<th>Instruction(s)</th>
<th>Description</th>
</tr>
</thead>

<td>Pushes $\log_2 e$ into ST</td>
</tr>
</tbody>
</table>

The following example and Figure 6.7 illustrate some of these instructions:

```plaintext
.Data
m1 REAL4 1.0
m2 REAL4 2.0
.Code
fld m1 ; Push m1 into first item
fld st(2) ; Push third item into first
fst m2 ; Copy first item to m2
fxch st(2) ; Exchange first and third items
fstp m1 ; Pop first item into m1
```

![Figure 6.7 Status of the Register Stack: Main Memory and Coprocessor](image-url)
Doing Arithmetic Calculations
Most of the coprocessor instructions for arithmetic operations have several forms, depending on the operand used. You do not need to specify the operand type in the
instruction if both operands are stack registers, since register values are always
10-byte real numbers. In most of the arithmetic instructions listed here, the
result replaces the destination register. The instructions include:

<table>
<thead>
<tr>

</tbody>
</table>
The following example illustrates several arithmetic instructions. The code solves quadratic equations, but does no error checking and fails for some values because it attempts to find the square root of a negative number. Both Help and the MATH.ASM sample file show a complete version of this procedure. The complete form uses the **FTST** (Test for Zero) instruction to check for a negative number or 0 before calculating the square root.

```
.DATA
a       REAL4   3.0
b       REAL4   7.0
cc      REAL4   2.0
posx    REAL4   0.0
negx    REAL4   0.0

.CODE

; Solve quadratic equation - no error checking
; The formula is: \(-b \pm \sqrt{b^2 - 4ac}\) / (2a)
fld1               ; Get constants 2 and 4
fadd    st,st      ; 2 at bottom
fld     st         ; Copy it
fmul    a          ; = 2a

fmul    st(1),st   ; = 4a
fxch
fmul    cc         ; = 4ac

fld    b          ; Load b
fmul    st,st      ; = b\(^2\)
fsubr   ; = b\(^2\) - 4ac
; Negative value here produces error
fsqrt   ; = square root(b\(^2\) - 4ac)
fld     b          ; Load b
fchs    ; Make it negative
fxch    ; Exchange

fld    st         ; Copy square root
fadd    st,st(2)   ; Plus version = -b + root(b\(^2\) - 4ac)
fxch    ; Exchange
fsubp   st(2),st   ; Minus version = -b - root(b\(^2\) - 4ac)

fdiv    st,st(2)   ; Divide plus version
fstp    posx       ; Store it
fdiv    st,st(2)   ; Divide minus version
fstp    negx       ; Store it
```
Controlling Program Flow

The math coprocessor has several instructions that set control flags in the status word. The 8087-family control flags can be used with conditional jumps to direct program flow in the same way that 8086-family flags are used. Since the coprocessor does not have jump instructions, you must transfer the status word to memory so that the flags can be used by 8086-family instructions.

An easy way to use the status word with conditional jumps is to move its upper byte into the lower byte of the processor flags, as shown in this example:

```
fstsw   mem16           ; Store status word in memory
fwait                   ; Make sure coprocessor is done
mov     ax, mem16       ; Move to AX
sahf                    ; Store upper word in flags
```

The `SAHF` (Store AH into Flags) instruction in this example transfers AH into the low bits of the flags register.

You can save several steps by loading the status word directly to AX on the 80287 with the `FSTSW` and `FNSTSW` instructions. This is the only case in which data can be transferred directly between processor and coprocessor registers, as shown in this example:

```
fstsw   ax
```

The coprocessor control flags and their relationship to the status word are described in “Control Registers,” following.

The 8087-family coprocessors provide several instructions for comparing operands and testing control flags. All these instructions compare the stack top (ST) to a source operand, which may either be specified or implied as ST(1).

The compare instructions affect the C3, C2, and C0 control flags, but not the C1 flag. Table 6.3 shows the flags’ settings for each possible result of a comparison or test.

<table>
<thead>
<tr>
<th>After FCOM</th>
<th>After FTTEST</th>
<th>C3</th>
<th>C2</th>
<th>C0</th>
</tr>
</thead>
<tbody>
<tr>
<td>ST &gt; source</td>
<td>ST is positive</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>ST &lt; source</td>
<td>ST is negative</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>ST = source</td>
<td>ST is 0</td>
<td>1</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>Not comparable</td>
<td>ST is NAN or projective infinity</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

Variations on the compare instructions allow you to pop the stack once or twice and to compare integers and zero. For each instruction, the stack top is always
the implied destination operand. If you do not give an operand, ST(1) is the implied source. With some compare instructions, you can specify the source as a memory or register operand.

All instructions summarized in the following list have implied operands: either ST as a single-destination operand or ST as the destination and ST(1) as the source. Each instruction in the list has implied operands. Some instructions have a wait version and a no-wait version. The no-wait versions have N as the second letter. The instructions for comparing and testing flags include:

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FCOM</td>
<td>Compares the stack top to the source. The source and destination are unaffected by the comparison.</td>
</tr>
<tr>
<td>FTST</td>
<td>Compares ST to 0.</td>
</tr>
<tr>
<td>FCOMP</td>
<td>Compares the stack top to the source and then pops the stack.</td>
</tr>
<tr>
<td>FUCOM, FUCOMP, FUCOMPP</td>
<td>Compares the source to ST and sets the condition codes of the status word according to the result (80386/486 only).</td>
</tr>
<tr>
<td>F[N]STSW mem2byte</td>
<td>Stores the status word in memory.</td>
</tr>
<tr>
<td>FXAM</td>
<td>Sets the value of the control flags based on the type of the number in ST.</td>
</tr>
<tr>
<td>FPREM</td>
<td>Finds a correct remainder for large operands. It uses the C2 flag to indicate whether the remainder returned is partial (C2 is set) or complete (C2 is clear). If the bit is set, the operation should be repeated. It also returns the least-significant three bits of the quotient in C0, C3, and C1.</td>
</tr>
<tr>
<td>FNOP</td>
<td>Copies the stack top onto itself, thus padding the executable file and taking up processing time without having any effect on registers or memory.</td>
</tr>
<tr>
<td>FDISI, FNDISI, FENI, FNENI</td>
<td>Enables or disables interrupts (8087 only).</td>
</tr>
<tr>
<td>FSETPM</td>
<td>Sets protected mode. Requires a .286P or .386P directive (80287, 80387, and 80486 only).</td>
</tr>
</tbody>
</table>

The following example illustrates some of these instructions. Notice how conditional blocks are used to enhance 80287 code.

```

Additional instructions for the 80387/486 are **FLDENVD** and **FLDENVW** for loading the environment; **FNSTENVD**, **FNSTENVW**, **FSTENVD**, and **FSTENVW** for storing the environment state; **FNSAVED**, **FNSAVEW**, **FSAVED**, and **FSAVEW** for saving the coprocessor state; and **FRSTORD** and **FRSTORW** for restoring the coprocessor state.

The size of the code segment, not the operand size, determines the number of bytes loaded or stored with these instructions. The instructions ending with **W** store the 16-bit form of the control register data, and the instructions ending with **D** store the 32-bit form. For example, in 16-bit mode **FSAVEW** saves the 16-bit control register data. If you need to store the 32-bit form of the control register data, use **FSAVED**.

**Control Registers**

Some of the flags of the seven 16-bit control registers control coprocessor operations, while others maintain the current status of the coprocessor. In this sense, they are much like the 8086-family flags registers (see Figure 6.8).

![Figure 6.8 Coprocessor Control Registers](image)

The status word register is the only commonly used control register. (The others are used mostly by systems programmers.) The format of the status word register is shown in Figure 6.9, which shows how the coprocessor control flags align with the processor flags. **C3** overwrites the zero flag, **C2** overwrites the parity flag, and **C0** overwrites the carry flag. **C1** overwrites an undefined bit, so it cannot be used directly with conditional jumps, although you can use the **TEST** instruction to...
check C1 in memory or in a register. The status word register also overwrites the sign and auxiliary-carry flags, so you cannot count on their being unchanged after the operation.

Figure 6.9 Coprocessor and Processor Control Flags

Using An Emulator Library

If you do not have a math coprocessor or an 80486 processor, you can do most floating-point operations by writing assembly-language procedures and accessing an emulator from a high-level language. All Microsoft high-level languages come with emulator libraries for all memory models.

To use emulator functions, first write your assembly-language procedure using coprocessor instructions. Then assemble the module with the /FPI option and link it with your high-level–language modules. You can enter options in the Programmer’s WorkBench (PWB) environment, or you can use the **OPTION EMULATOR** in your source code.

In emulation mode, the assembler generates instructions for the linker that the Microsoft emulator can use. The form of the **OPTION** directive in the following example tells the assembler to use emulation mode. This option (introduced in Chapter 1) can be defined only once in a module.

**OPTION EMULATOR**
You can use emulator functions in a stand-alone assembler program by assembling with the /Cx command-line option and linking with the appropriate emulator library. The following fragment outlines a small-model program that contains floating-point instructions served by an emulator:

```
.MODEL small, c
OPTION EMULATOR

PUBLIC main
.CODE
main: ; Program entry point must have name 'main'
.STARTUP ; Floating-point instructions emulated
fadd st, st
fldpi
```

Emulator libraries do not allow for all of the coprocessor instructions. The following floating-point instructions are not emulated:

- FBLD
- FBSTP
- FCOS
- FDECSTP
- FINCSTP
- FINIT
- FLDENV
- FNOP
- FPREM1
- FRSTOR
- FRSTORW
- FRSTORD
- FSAVE
- FSAVEW
- FSAVED
- FSTENV
- FUCOM
- FUCOMP
- FUCOMPP
- FXTRACT
- FUSIN
- FSINCOS
- FSIN
- FSINCOS

For information about writing assembly-language procedures for high-level languages, see Chapter 12, “Mixed-Language Programming.”

### Using Binary Coded Decimal Numbers

Binary coded decimal (BCD) numbers allow calculations on large numbers without rounding errors. This characteristic makes BCD numbers a common choice for monetary calculations. Although BCDs can represent integers of any precision, the 8087-based coprocessors accommodate BCD numbers only in the range ±999,999,999,999,999.

This section explains how to define BCD numbers, how to access them with a math coprocessor or emulator, and how to perform simple BCD calculations on the main processor.

#### Defining BCD Constants and Variables

Unpacked BCD numbers are made up of bytes containing a single decimal digit in the lower 4 bits of each byte. Packed BCD numbers are made up of bytes
containing two decimal digits: one in the upper 4 bits and one in the lower 4 bits. The leftmost digit holds the sign (0 for positive, 1 for negative).

Packed BCD numbers are encoded in the 8087 coprocessor's packed BCD format. They can be up to 18 digits long, packed two digits per byte. The assembler zero-pads BCDs initialized with fewer than 18 digits. Digit 20 is the sign bit, and digit 19 is reserved.

When you define an integer constant with the TBYTE directive and the current radix is decimal (t), the assembler interprets the number as a packed BCD number.

The syntax for specifying packed BCDs is the same as for other integers.

```
pos1    TBYTE   1234567890  ; Encoded as 00000000001234567890h
neg1    TBYTE   -1234567890 ; Encoded as 80000000001234567890h
```

Unpacked BCD numbers are stored one digit to a byte, with the value in the lower 4 bits. They can be defined using the BYTE directive. For example, an unpacked BCD number could be defined and initialized as follows:

```
unpackedr BYTE 1,5,8,2,5,2,9   ; Initialized to 9,252,851
unpackedf BYTE 9,2,5,2,8,5,1   ; Initialized to 9,252,851
```

As these two lines show, you can arrange digits backward or forward, depending on how you write the calculation routines that handle the numbers.

**BCD Calculations on a Coprocessor**

As the previous section explains, BCDs differ from other numbers only in the way a program stores them in memory. Internally, a math coprocessor does not distinguish BCD integers from any other type. The coprocessor can load, calculate, and store packed BCD integers up to 18 digits long.

The coprocessor instruction

```
fbld bcd1
```

pushes the packed BCD number at bcd1 onto the coprocessor stack. When your code completes calculations on the number, place the result back into memory in BCD format with the instruction

```
fbstp bcd1
```

which discards the variable from the stack top.
BCD Calculations on the Main Processor

The 8086-family of processors can perform simple arithmetic operations on BCD integers, but only one digit at a time. The main processor, like the coprocessor, operates internally on the number’s binary value. It requires additional code to translate the binary result back into BCD format.

The main processor provides instructions specifically designed to translate to and from BCD format. These instructions are called “ASCII-adjust” and “decimal-adjust” instructions. They get their names from Intel mnemonics that use the term “ASCII” to refer to unpacked BCD numbers and “decimal” to refer to packed BCD numbers.

Unpacked BCD Numbers

When a calculation using two one-digit values produces a two-digit result, the instructions **AAA**, **AAS**, **AAM**, and **AAD** place the first digit in AL and the second in AH. If the digit in AL needs to carry to or borrow from the digit in AH, the instructions set the carry and auxiliary carry flags. The four ASCII-adjust instructions for unpacked BCDs are:

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>AAA</strong></td>
<td>Adjusts after an addition operation.</td>
</tr>
<tr>
<td><strong>AAS</strong></td>
<td>Adjusts after a subtraction operation.</td>
</tr>
<tr>
<td><strong>AAM</strong></td>
<td>Adjusts after a multiplication operation. Always use with <strong>MUL</strong>, not with <strong>IMUL</strong>.</td>
</tr>
<tr>
<td><strong>AAD</strong></td>
<td>Adjusts before a division operation. Unlike other BCD instructions, <strong>AAD</strong> converts a BCD value to a binary value before the operation. After the operation, use <strong>AAM</strong> to adjust the quotient. The remainder is lost. If you need the remainder, save it in another register before adjusting the quotient. Then move it back to AL and adjust if necessary.</td>
</tr>
</tbody>
</table>

For processor arithmetic on unpacked BCD numbers, you must do the 8-bit arithmetic calculations on each digit separately, and assign the result to the AL register. After each operation, use the corresponding BCD instruction to adjust the result. The ASCII-adjust instructions do not take an operand and always work on the value in the AL register.
The following examples show how to use each of these instructions in BCD addition, subtraction, multiplication, and division.

; To add 9 and 3 as BCDs:
    mov ax, 9       ; Load 9
    mov bx, 3       ; and 3 as unpacked BCDs
    add al, bl      ; Add 09h and 03h to get 0Ch
    aaa              ; Adjust 0Ch in AL to 02h,
                      ; increment AH to 01h, set carry
    ; Result 12 (unpacked BCD in AX)

; To subtract 4 from 13:
    mov ax, 103h    ; Load 13
    mov bx, 4       ; and 4 as unpacked BCDs
    sub al, bl      ; Subtract 4 from 3 to get FFh (-1)
    aas              ; Adjust 0FFh in AL to 9,
                      ; decrement AH to 0, set carry
    ; Result 9 (unpacked BCD in AX)

; To multiply 9 times 3:
    mov ax, 903h    ; Load 9 and 3 as unpacked BCDs
    mul ah          ; Multiply 9 and 3 to get 1Bh
    aam              ; Adjust 1Bh in AL
                      ; to get 27 (unpacked BCD in AX)

; To divide 25 by 2:
    mov ax, 205h    ; Load 25
    mov bl, 2       ; and 2 as unpacked BCDs
    aad              ; Adjust 0205h in AX
                      ; to get 19h in AX
    div bl          ; Divide by 2 to get
                      ; quotient 0Ch in AL
                      ; remainder 1 in AH
    aam              ; Adjust 0Ch in AL
                      ; to 12 (unpacked BCD in AX)
                      ; (remainder destroyed)

If you process multidigit BCD numbers in loops, each digit is processed and adjusted in turn.

**Packed BCD Numbers**

Packed BCD numbers are made up of bytes containing two decimal digits: one in the upper 4 bits and one in the lower 4 bits. The 8086-family processors provide instructions for adjusting packed BCD numbers after addition and subtraction. You must write your own routines to adjust for multiplication and division.
For processor calculations on packed BCD numbers, you must do the 8-bit arithmetic calculations on each byte separately, placing the result in the AL register. After each operation, use the corresponding decimal-adjust instruction to adjust the result. The decimal-adjust instructions do not take an operand and always work on the value in the AL register.

The 8086-family processors provide the instructions DAA (Decimal Adjust after Addition) and DAS (Decimal Adjust after Subtraction) for adjusting packed BCD numbers after addition and subtraction.

These examples use DAA and DAS to add and subtract BCDs.

; To add 88 and 33:
mov ax, 8833h ; Load 88 and 33 as packed BCDs
add al, ah ; Add 88 and 33 to get 0BBh
da ; Adjust 0BBh to 121 (packed BCD: 1 in carry and 21 in AL

; To subtract 38 from 83:
mov ax, 3883h ; Load 83 and 38 as packed BCDs
sub al, ah ; Subtract 38 from 83 to get 04Bh
das ; Adjust 04Bh to 45 (packed BCD: 0 in carry and 45 in AL

Unlike the ASCII-adjust instructions, the decimal-adjust instructions never affect AH. The assembler sets the auxiliary carry flag if the digit in the lower 4 bits carries to or borrows from the digit in the upper 4 bits, and it sets the carry flag if the digit in the upper 4 bits needs to carry to or borrow from another byte.

Multidigit BCD numbers are usually processed in loops. Each byte is processed and adjusted in turn.
CHAPTER 7

Controlling Program Flow

Very few programs execute all lines sequentially from .STARTUP to .EXIT. Rather, complex program logic and efficiency dictate that you control the flow of your program—jumping from one point to another, repeating an action until a condition is reached, and passing control to and from procedures. This chapter describes various ways for controlling program flow and several features that simplify coding program-control constructs.

The first section covers jumps from one point in the program to another. It explains how MASM 6.1 optimizes both unconditional and conditional jumps under certain circumstances, so that you do not have to specify every attribute. The section also describes instructions you can use to test conditional jumps.

The next section describes loop structures that repeat actions or evaluate conditions. It discusses MASM directives, such as .WHILE and .REPEAT, that generate appropriate compare, loop, and jump instructions for you, and the .IF, .ELSE, and .ELSEIF directives that generate jump instructions.

The “Procedures” section in this chapter explains how to write an assembly-language procedure. It covers the extended functionality for PROC, a PROTO directive that lets you write procedure prototypes similar to those used in C, an INVOKE directive that automates parameter passing, and options for the stack-frame setup inside procedures.

The last section explains how to pass program control to an interrupt routine.

Jumps

Jumps are the most direct way to change program control from one location to another. At the processor level, jumps work by changing the value of the IP (Instruction Pointer) register to a target offset and, for far jumps, by changing the CS register to a new segment address. Jump instructions fall into only two categories: conditional and unconditional.
Unconditional Jumps

The **JMP** instruction transfers control unconditionally to another instruction. **JMP**’s single operand contains the address of the target instruction.

Unconditional jumps skip over code that should not be executed, as shown here:

```
; Handle one case
label1: .
    ...
    jmp continue

; Handle second case
label2: .
    ...
    jmp continue

continue:
```

The distance of the target from the jump instruction and the size of the operand determine the assembler’s encoding of the instruction. The longer the distance, the more bytes the assembler uses to code the instruction. In versions of MASM prior to 6.0, unconditional **NEAR** jumps sometimes generated inefficient code, but MASM can now optimize unconditional jumps.

Jump Optimizing

The assembler determines the smallest encoding possible for the direct unconditional jump. MASM does not require a distance operator, so you do not have to determine the correct distance of the jump. If you specify a distance, it overrides any assembler optimization. If the specified distance falls short of the target address, the assembler generates an error. If the specified distance is longer than the jump requires, the assembler encodes the given distance and does not optimize it.

The assembler optimizes jumps when the following conditions are met:

- You do not specify **SHORT, NEAR, FAR, NEAR16, NEAR32, FAR16, FAR32, or PROC** as the distance of the target.

- The target of the jump is not external and is in the same segment as the jump instruction. If the target is in a different segment (but in the same group), it is treated as though it were external.
If these two conditions are met, MASM uses the instruction, distance, and size of the operand to determine how to optimize the encoding for the jump. No syntax changes are necessary.

**Note** This information about jump optimizing also applies to conditional jumps on the 80386/486.

### Indirect Operands

An indirect operand provides a pointer to the target address, rather than the address itself. A pointer is a variable that contains an address. The processor distinguishes indirect (pointer) operands from direct (address) operands by the instruction’s context.

You can specify the pointer’s size with the `WORD`, `DWORD`, or `FWORD` attributes. Default sizes are based on `.MODEL` and the default segment size.

```assembly
jmp     [bx]          ; Uses .MODEL and segment size defaults
jmp     WORD PTR [bx] ; A NEAR16 indirect call
```

If the indirect operand is a register, the jump is always a `NEAR16` jump for a 16-bit register, and `NEAR32` for a 32-bit register:

```assembly
jmp     bx            ; NEAR16 jump
jmp     ebx           ; NEAR32  jump
```

A `DWORD` indirect operand, however, is ambiguous to the assembler.

```assembly
jmp     DWORD PTR [var]       ; A NEAR32 jump in a 32-bit segment; a FAR16 jump in a 16-bit segment
```

In this case, your code must clear the ambiguity with the `NEAR32` or `FAR16` keywords. The following example shows how to use `TYPEDEF` to define `NEAR32` and `FAR16` pointer types.

```assembly
NFP     TYPEDEF PTR NEAR32
FFP     TYPEDEF PTR FAR16
```

```assembly
jmp     NFP PTR [var] ; NEAR32 indirect jump
jmp     FFP PTR [var] ; FAR16   indirect jump
```

You can use an unconditional jump as a form of conditional jump by specifying the address in a register or indirect memory operand. Also, you can use indirect memory operands to construct jump tables that work like C `switch` statements, Pascal `CASE` statements, or Basic `ON GOTO`, `ON GOSUB`, or `SELECT CASE` statements, as shown in the following example.
NPVOI D  TYPEDEF NEAR PTR
.DAT
ctl_tbl NPVOD  extended, ; Null key (extended code)
    ctl_a, ; Address of CONTROL-A key routine
    ctl_b ; Address of CONTROL-B key routine
.CODE

mov  ah, 8h ; Get a key
int  21h
cbw                    ; Stretch AL into AX
mov  bx, ax ; Copy
shl  bx, 1 ; Convert to address
jmp  ctl_tbl[bx] ; Jump to key routine

extended:
    mov  ah, 8h ; Get second key of extended key
    int  21h
    jmp  next ; Use another jump table
.extended : ; for extended keys
    jmp  next

ctl_a: ; CONTROL-A code here

ctl_b: ; CONTROL-B code here

next: ; Continue

In this instance, the indirect memory operands point to addresses of routines for handling different keystrokes.

Conditional Jumps

The most common way to transfer control in assembly language is to use a conditional jump. This is a two-step process:

1. First test the condition.
2. Then jump if the condition is true or continue if it is false.
All conditional jumps except two (JCXZ and JECXZ) use the processor flags for their criteria. Thus, any statement that sets or clears a flag can serve as a test basis for a conditional jump. The jump statement can be any one of 30 conditional-jump instructions. A conditional-jump instruction takes a single operand containing the target address. You cannot use a pointer value as a target as you can with unconditional jumps.

Jumping Based on the CX Register

JCXZ and JECXZ are special conditional jumps that do not consult the processor flags. Instead, as their names imply, these instructions cause a jump only if the CX or ECX register is zero. The use of JCXZ and JECXZ with program loops is covered in the next section, “Loops.”

Jumping Based on the Processor Flags

The remaining conditional jumps in the processor’s repertoire all depend on the status of the flags register. As the following list shows, several conditional jumps have two or three names — JE (Jump if Equal) and JZ (Jump if Zero), for example. Shared names assemble to exactly the same machine instruction, so you may choose whichever mnemonic seems more appropriate. Jumps that depend on the status of the flags register include:

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Jumps if</th>
</tr>
</thead>
<tbody>
<tr>
<td>JC/JB/JNAE</td>
<td>Carry flag is set</td>
</tr>
<tr>
<td>JNC/JNB/JAE</td>
<td>Carry flag is clear</td>
</tr>
<tr>
<td>JBE/JNA</td>
<td>Either carry or zero flag is set</td>
</tr>
<tr>
<td>JA/JNBE</td>
<td>Carry and zero flag are clear</td>
</tr>
<tr>
<td>JE/JZ</td>
<td>Zero flag is set</td>
</tr>
<tr>
<td>JNE/JNZ</td>
<td>Zero flag is clear</td>
</tr>
<tr>
<td>JL/JNGE</td>
<td>Sign flag ≠ overflow flag</td>
</tr>
<tr>
<td>JGE/JNL</td>
<td>Sign flag = overflow flag</td>
</tr>
<tr>
<td>JLE/JNG</td>
<td>Zero flag is set or sign ≠ overflow</td>
</tr>
<tr>
<td>JG/JNLE</td>
<td>Zero flag is clear and sign = overflow</td>
</tr>
<tr>
<td>JS</td>
<td>Sign flag is set</td>
</tr>
<tr>
<td>JNS</td>
<td>Sign flag is clear</td>
</tr>
<tr>
<td>JO</td>
<td>Overflow flag is set</td>
</tr>
<tr>
<td>JNO</td>
<td>Overflow flag is clear</td>
</tr>
<tr>
<td>JP/JPE</td>
<td>Parity flag is set (even parity)</td>
</tr>
<tr>
<td>JNP/JPO</td>
<td>Parity flag is clear (odd parity)</td>
</tr>
</tbody>
</table>

The last two jumps in the list, JPE (Jump if Parity Even) and JPO (Jump if Parity Odd), are useful only for communications programs. The processor sets
the parity flag if an operation produces a result with an even number of set bits. A communications program can compare the flag against the parity bit received through the serial port to test for transmission errors.

The conditional jumps in the preceding list can follow any instruction that changes the processor flags, as these examples show:

```assembly
; Uses JO to handle overflow condition
add    ax, bx          ; Add two values
j o    overflow        ; If value too large, adjust

; Uses JNZ to check for zero as the result of subtraction
sub    ax, bx          ; Subtract
m o v  cx, Count       ; First, initialize CX
j n z  skip            ; If the result is not zero, continue
c a l l  zhandler      ; Else do special case
```

As the second example shows, the jump does not have to immediately follow the instruction that alters the flags. Since MOV does not change the flags, it can appear between the SUB instruction and the dependent jump.

There are three categories of conditional jumps:
- Comparison of two values
- Individual bit settings in a value
- Whether a value is zero or nonzero

**Jumps Based on Comparison of Two Values**

The CMP instruction is the most common way to test for conditional jumps. It compares two values without changing either, then sets or clears the processor flags according to the results of the comparison.

Internally, the CMP instruction is the same as the SUB instruction, except that CMP does not change the destination operand. Both set flags according to the result of the subtraction.
You can compare signed or unsigned values, but you must choose the subsequent conditional jump to reflect the correct value type. For example, **JL** (Jump if Less Than) and **JB** (Jump if Below) may seem conceptually similar, but a failure to understand the difference between them can result in program bugs. Table 7.1 shows the correct conditional jumps for comparisons of signed and unsigned values. The table shows the zero, carry, sign, and overflow flags as ZF, CF, SF, and OF, respectively.

<table>
<thead>
<tr>
<th>Signed Comparisons Instruction</th>
<th>Jump if True</th>
<th>Unsigned Comparisons Instruction</th>
<th>Jump if True</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>JE</strong></td>
<td>ZF = 1</td>
<td><strong>JE</strong></td>
<td>ZF = 1</td>
</tr>
<tr>
<td><strong>JNE</strong></td>
<td>ZF = 0</td>
<td><strong>JNE</strong></td>
<td>ZF = 0</td>
</tr>
<tr>
<td><strong>JG/JNLE</strong></td>
<td>ZF = 0 and SF = OF</td>
<td><strong>JA/JNBE</strong></td>
<td>CF = 0 and ZF = 0</td>
</tr>
<tr>
<td><strong>JLE/JNG</strong></td>
<td>ZF = 1 or SF ≠ OF</td>
<td><strong>JBE/JNA</strong></td>
<td>CF = 1 or ZF = 1</td>
</tr>
<tr>
<td><strong>JL/JNGE</strong></td>
<td>SF ≠ OF</td>
<td><strong>JB/JNAE</strong></td>
<td>CF = 1</td>
</tr>
<tr>
<td><strong>JGE/JNL</strong></td>
<td>SF = OF</td>
<td><strong>JAE/JNB</strong></td>
<td>CF = 0</td>
</tr>
</tbody>
</table>

The mnemonic names of jumps always refer to the comparison of **CMP**’s first operand (destination) with the second operand (source). For instance, in this example, **JG** tests whether the first operand is greater than the second.

```assembly
cmp     ax, bx ; Compare AX and BX
jg      next1  ; Equivalent to: If ( AX > BX ) goto next1
jl      next2  ; Equivalent to: If ( AX < BX ) goto next2
```

**Jumps Based on Bit Settings**

The individual bit settings in a single value can also serve as the criteria for a conditional jump. The **TEST** instruction tests whether specific bits in an operand are on or off (set or clear), and sets the zero flag accordingly.
The **TEST** instruction is the same as the **AND** instruction, except that **TEST** changes neither operand. The following example shows an application of **TEST**.

```
.DATA
bits BYTE ?
.CODE

; If bit 2 or bit 4 is set, then call task_a
  ; Assume "bits" is 0D3h 11010011
  test bits, 10100y  ; If 2 or 4 is set AND 00010100
  jz      skip1           ;                          --------
  call    task_a          ; Then call task_a         00010000
skip1:                          ; Jump taken

; If bits 2 and 4 are clear, then call task_b
  ; Assume "bits" is 0E9h 11101001
  test bits, 10100y  ; If 2 and 4 are clear AND 00010100
  jnz     skip2           ;                          --------
  call    task_b          ; Then call task_b         00000000
skip2:                          ; Jump taken
```

The source operand for **TEST** is often a mask in which the test bits are the only bits set. The destination operand contains the value to be tested. If all the bits set in the mask are clear in the destination operand, **TEST** sets the zero flag. If any of the flags set in the mask are also set in the destination operand, **TEST** clears the zero flag.

The 80386/486 processors provide additional bit-testing instructions. The **BT** (Bit Test) series of instructions copy a specified bit from the destination operand to the carry flag. A **JC** or **JNC** can then route program flow depending on the result. For variations on the **BT** instruction, see the **Reference**.

**Jumps Based on a Value of Zero**

A program often needs to jump based on whether a particular register contains a value of zero. We’ve seen how the **JCXZ** instruction jumps depending on the value in the CX register. You can test for zero in other data registers nearly as efficiently with the **OR** instruction. A program can **OR** a register with itself without changing the register’s contents, then act on the resulting flags status. For example, the following example tests whether **BX** is zero:

```
or      bx, bx          ; Is BX = 0?
jz      is_zero         ; Jump if so
```
This code is functionally equivalent to:

```
cmp bx, 0       ; Is BX = 0?
je is_zero     ; Jump if so
```

but produces smaller and faster code, since it does not use an immediate number as an operand. The same technique also lets you test a register’s sign bit:

```
or dx, dx       ; Is DX sign bit set?
js sign_set     ; Jump if so
```

### Jump Extending

Unlike an unconditional jump, a conditional jump cannot reference a label more than 128 bytes away. For example, the following statement is valid as long as `target` is within a distance of 128 bytes:

```
; Jump to target less than 128 bytes away
jz target       ; If previous operation resulted in zero, jump to target
```

However, if `target` is too distant, the following sequence is necessary to enable a longer jump. Note this sequence is logically equivalent to the preceding example:

```
; Jumps to distant targets previously required two steps
jnz skip         ; If previous operation result is NOT zero, jump to "skip"
jmp target      ; Otherwise, jump to target

skip:
```

MASM can automate jump-extending for you. If you target a conditional jump to a label farther than 128 bytes away, MASM rewrites the instruction with an unconditional jump, which ensures that the jump can reach its target. If `target` lies within a 128-byte range, the assembler encodes the instruction `jz target` as is. Otherwise, MASM generates two substitute instructions:

```
jne $ + 2 + (length in bytes of the next instruction)
jmp NEAR PTR target
```

The assembler generates this same code sequence if you specify the distance with `NEAR PTR`, `FAR PTR`, or `SHORT`. Therefore,

```
jz NEAR PTR target
```
even if `target` is less than 128 bytes away.

MASM enables automatic jump expansion by default, but you can turn it off with the `NOLJMP` form of the `OPTION` directive. For information about the `OPTION` directive, see page 24.

If the assembler generates code to extend a conditional jump, it issues a level 3 warning saying that the conditional jump has been lengthened. You can set the warning level to 1 for development and to level 3 for a final optimizing pass to see if you can shorten jumps by reorganizing.

If you specify the distance for the jump and the target is out of range for that distance, a “Jump out of Range” error results.

Since the `JCXZ` and `JE CXZ` instructions do not have logical negations, expansion of the jump instruction to handle targets with unspecified distances cannot be performed for those instructions. Therefore, the distance must always be short.

The size and distance of the target operand determines the encoding for conditional or unconditional jumps to externals or targets in different segments. The jump-extending and optimization features do not apply in this case.

---

**Note** Conditional jumps on the 80386 and 80486 processors can be to targets up to 32K away, so jump extension occurs only for targets greater than that distance.

---

**Anonymous Labels**

When you code jumps in assembly language, you must invent many label names. One alternative to continually thinking up new label names is to use anonymous labels, which you can use anywhere in your program. But because anonymous labels do not provide meaningful names, they are best used for jumping over only a few lines of code. You should mark major divisions of a program with actual named labels.

Use two at signs (`@@`) followed by a colon (:) as an anonymous label. To jump to the nearest preceding anonymous label, use `@B` (back) in the jump instruction’s operand field; to jump to the nearest following anonymous label, use `@F` (forward) in the operand field.

The jump in the following example targets an anonymous label:
The items \@B and \@F always refer to the nearest occurrences of \@@:, so there is never any conflict between different anonymous labels.

**Decision Directives**

The high-level structures you can use for decision-making are the \.IF, \.ELSEIF, and \.ELSE statements. These directives generate conditional jumps. The expression following the \.IF directive is evaluated, and if true, the following instructions are executed until the next \.ENDIF, \.ELSE, or \.ELSEIF directive is reached. The \.ELSE statements execute if the expression is false. Using the \.ELSEIF directive puts a new expression inside the alternative part of the original \.IF statement to be evaluated. The syntax is:

\[
\text{\texttt{.IF condition1}} \\
\text{\texttt{statements}} \\
[[\text{\texttt{.ELSEIF condition2}} \\
\text{\texttt{statements}}]] \\
[[\text{\texttt{.ELSE}} \\
\text{\texttt{statements}}]] \\
\text{\texttt{.ENDIF}}
\]

The decision structure

\[
\text{\texttt{.IF \ cx == 20}} \\
\text{\texttt{mov dx, 20}} \\
\text{\texttt{.ELSE}} \\
\text{\texttt{mov dx, 30}} \\
\text{\texttt{.ENDIF}}
\]

generates this code:

```
  .IF cx == 20
  cmp cx, 014h
  jne @C0001
  mov dx, 20
  .ELSE
  mov dx, 30
  .ENDIF
```

```
0017  83 F9 14        *         cmp    cx, 014h
001A  75 05           *         jne    @C0001
001C  BA 0014                   mov    dx, 20
  .ELSE
001F  EB 03           *         jmp    @C0003
0021                  *@C0003:
0021  BA 001E                   mov   dx, 30
  .ENDIF
0024                  *@C0003:
```
Loops

Loops repeat an action until a termination condition is reached. This condition can be a counter or the result of an expression’s evaluation. MASM 6.1 offers many ways to set up loops in your programs. The following list compares MASM loop structures:

<table>
<thead>
<tr>
<th>Instructions</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>LOOP</td>
<td>Automatically decrements CX. When CX = 0, the loop ends. The top of the loop cannot be greater than 128 bytes from the LOOP instruction. (This is true for all LOOP instructions.)</td>
</tr>
<tr>
<td>LOOPE/LOOPZ, LOOPNE/LOOPNZ</td>
<td>Loops while equal or not equal. Checks both CX and the state of the zero flag. LOOPZ ends when either CX=0 or the zero flag is clear, whichever occurs first. LOOPNZ ends when either CX=0 or the zero flag is set, whichever occurs first. LOOPE and LOOPZ assemble to the same machine instruction, as do LOOPNE and LOOPNZ. Use whichever mnemonic best fits the context of your loop. Set CX to a number out of range if you don’t want a count to control the loop.</td>
</tr>
<tr>
<td>JCXZ, JECXZ</td>
<td>Branches to a label only if CX = 0 or ECX = 0. Unlike other conditional-jump instructions, which can jump to either a near or a short label under the 80386 or 80486, JCXZ and JECXZ always jump to a short label. Conditional jumps Acts only if certain conditions met. Necessary if several conditions must be tested. See “Conditional Jumps,” page 164.</td>
</tr>
</tbody>
</table>

The following examples illustrate these loop constructions.

;; The LOOP instruction: For 200 to 0 do task
mov    cx, 200  ; Set counter
next:   .       ; Do the task here
          .
loop    next    ; Do again
          ; Continue after loop

;; The LOOPNE instruction: While AX is not 'Y', do task
mov    cx, 256  ; Set count too high to interfere
wend:   .       ; But don't do more than 256 times
          ; Some statements that change AX
          .
cmp    al, 'Y'  ; Is it Y or too many times?
loopne  wend    ; No? Repeat
          ; Yes? Continue

The JCXZ and JECXZ instructions provide an efficient way to avoid executing loops when the loop counter CX is empty. For example, consider the following loops:
mov cx, LoopCount ; Load loop counter

next: . ; Iterate loop CX times

loop next ; Do again

If LoopCount is zero, CX decrements to -1 on the first pass. It then must decrement 65,535 more times before reaching 0. Use a JCXZ to avoid this problem:

mov cx, LoopCount ; Load loop counter
jcxz done ; Skip loop if count is 0

next: . ; Else iterate loop CX times

loop next ; Do again
done: ; Continue after loop

Loop-Generating Directives

The high-level control structures generate loop structures for you. These directives are similar to the while and repeat loops of C or Pascal, and can make your assembly programs easier to code and to read. The assembler generates the appropriate assembly code. These directives are summarized as follows:

<table>
<thead>
<tr>
<th>Directives</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>.WHILE ... .ENDW</td>
<td>The statements between .WHILE condition and .ENDW execute while the condition is true.</td>
</tr>
<tr>
<td>.REPEAT ... .UNTIL</td>
<td>The loop executes at least once and continues until the condition given after .UNTIL is true. Generates conditional jumps.</td>
</tr>
<tr>
<td>.REPEAT ... .UNTILCXZ</td>
<td>Compares label to an expression and generates appropriate loop instructions.</td>
</tr>
<tr>
<td>.BREAK</td>
<td>End a .REPEAT or a .WHILE loop unconditionally.</td>
</tr>
<tr>
<td>.CONTINUE</td>
<td>Jump unconditionally past any remaining code to bottom of loop.</td>
</tr>
</tbody>
</table>
These constructs work much as they do in a high-level language such as C or Pascal. Keep in mind the following points:

- These directives generate appropriate processor instructions. They are not new instructions.
- They require proper use of signed and unsigned data declarations.

These directives cause a set of instructions to execute based on the evaluation of some condition. This condition can be an expression that evaluates to a signed or unsigned value, an expression using the binary operators in C (`&&`, `||`, or `!`), or the state of a flag. For more information about expression operators, see page 178.

The evaluation of the condition requires the assembler to know if the operands in the condition are signed or unsigned. To state explicitly that a named memory location contains a signed integer, use the signed data allocation directives `SBYTE`, `SWORD`, and `SDWORD`.

**.WHILE Loops**

As with `while` loops in C or Pascal, the test condition for `.WHILE` is checked before the statements inside the loop execute. If the test condition is false, the loop does not execute. While the condition is true, the statements inside the loop repeat.

Use the `.ENDW` directive to mark the end of the `.WHILE` loop. When the condition becomes false, program execution begins at the first statement following the `.ENDW` directive. The `.WHILE` directive generates appropriate compare and jump statements. The syntax is:

```
.WHILE condition
  statements
.ENDW
```

For example, this loop copies the contents of one buffer to another until a `$` character (marking the end of the string) is found:

```
.DAT
  buf1    BYTE "This is a string","$
  buf2    BYTE 100 DUP (?)
.CODE
  sub     bx, bx                 ; Zero out bx
  .WHILE  (buf1[bx] ! = '$')
    mov     al, buf1[bx]           ; Get a character
    mov     buf2[bx], al           ; Move it to buffer 2
    inc     bx                     ; Count forward
  .ENDW
```
.REPEAT Loops
MASM’s .REPEAT directive allows for loop constructions like the do loop of C and the REPEAT loop of Pascal. The loop executes until the condition following the .UNTIL (or .UNTILCXZ) directive becomes true. Since the condition is checked at the end of the loop, the loop always executes at least once. The .REPEAT directive generates conditional jumps. The syntax is:

```
.REPEAT
  statements
.UNTIL condition
.REPEAT
  statements
.UNTILCXZ [[condition]]
```

where condition can also be expr1 == expr2 or expr1 != expr2. When two conditions are used, expr2 can be an immediate expression, a register, or (if expr1 is a register) a memory location.

For example, the following code fills a buffer with characters typed at the keyboard. The loop ends when the ENTER key (character 13) is pressed:

```
.DATA
  buffer BYTE 100 DUP (0)
.CODE
  sub bx, bx ; Zero out bx
  .REPEAT
  mov ah, 01h
  int 21h ; Get a key
  mov buffer[bx], al ; Put it in the buffer
  inc bx ; Increment the count
  .UNTIL (al == 13) ; Continue until al is 13
```
The .UNTIL directive generates conditional jumps, but the .UNTILCXZ directive generates a LOOP instruction, as shown by the listing file code for these examples. In a listing file, assembler-generated code is preceded by an asterisk.

```
ASSUME bx:PTR SomeStruct

.REPEAT
*@@0001:
    inc ax
.UNTIL ax==6
*
    cmp ax, 006h
*
    jne @@0001
.REPEAT
*@@0003:
    mov ax, 1
.UNTILCXZ
*
    loop @@0003
.REPEAT
*@@0004:
    .UNTILCXZ [bx].field != 6
*
    cmp [bx].field, 006h
*
    loope @@0004
```

**.BREAK and .CONTINUE Directives**

The .BREAK and .CONTINUE directives terminate a .REPEAT or .WHILE loop prematurely. These directives allow an optional .IF clause for conditional breaks. The syntax is:

```
.BREAK [[.IF condition]]
.CONTINUE [[.IF condition]]
```

Note that .ENDIF is not used with the .IF forms of .BREAK and .CONTINUE in this context. The .BREAK and .CONTINUE directives work the same way as the break and continue instructions in C. Execution continues at the instruction following the .UNTIL, .UNTILCXZ, or .ENDW of the nearest enclosing loop.

Instead of ending the loop execution as .BREAK does, .CONTINUE causes loop execution to jump directly to the code that evaluates the loop condition of the nearest enclosing loop.

The following loop accepts only the keys in the range ‘0’ to ‘9’ and terminates when you press ENTER.
.WHILE 1  ; Loop forever
mov ah, 08h  ; Get key without echo
int 21h
BREAK .IF al == 13  ; If ENTER, break out of the loop
CONTINUE .IF (al < '0') || (al > '9')  ; If not a digit, continue looping
mov dl, al  ; Save the character for processing
mov ah, 02h  ; Output the character
int 21h
ENDW

If you assemble the preceding source code with the /Fl and /Sg command-line options and then view the results in the listing file, you will see this code:

```
.WHILE 1
 0017 B4 08  mov ah, 08h
 0019 CD 21  int 21h
    BREAK .IF al == 13
 001B 3C 0D  cmp al, 00Dh
    CONTINUE .IF (al < '0') || (al > '9')
 001F 3C 30  cmp al, '0'
 0021 72 F4  je @C0002
 0023 3C 39  cmp al, '9'
 0025 77 F0  ja @C0001
 0027 8A D0  mov dl, al
 0029 B4 02  mov ah, 02h
 002B CD 21  int 21h
    ENDW
 002D EB EB  jmp @C0001
 002F
```

The high-level control structures can be nested. That is, .REPEAT or .WHILE loops can contain .REPEAT or .WHILE loops as well as .IF statements.

If the code generated by a .WHILE loop, .REPEAT loop, or .IF statement generates a conditional or unconditional jump, MASM encodes the jump using the jump extension and jump optimization techniques described in “Unconditional Jumps,” page 162, and “Conditional Jumps,” page 164.
Writing Loop Conditions

You can express the conditions of the `.IF`, `.REPEAT`, and `.WHILE` directives using relational operators, and you can express the attributes of the operand with the `PTR` operator. To write loop conditions, you also need to know how the assembler evaluates the operators and operands in the condition. This section explains the operators, attributes, precedence level, and expression evaluation order for the conditions used with loop-generating directives.

Expression Operators

The binary relational operators in MASM 6.1 are the same binary operators used in C. These operators generate MASM compare, test, and conditional jump instructions. High-level control instructions include:

<table>
<thead>
<tr>
<th>Operator</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>==</code></td>
<td>Equal</td>
</tr>
<tr>
<td><code>!=</code></td>
<td>Not equal</td>
</tr>
<tr>
<td><code>&gt;</code></td>
<td>Greater than</td>
</tr>
<tr>
<td><code>&gt;=</code></td>
<td>Greater than or equal to</td>
</tr>
<tr>
<td><code>&lt;</code></td>
<td>Less than</td>
</tr>
<tr>
<td><code>&lt;=</code></td>
<td>Less than or equal to</td>
</tr>
<tr>
<td><code>&amp;</code></td>
<td>Bit test</td>
</tr>
<tr>
<td><code>!</code></td>
<td>Logical NOT</td>
</tr>
<tr>
<td><code>&amp;&amp;</code></td>
<td>Logical AND</td>
</tr>
<tr>
<td>`</td>
<td></td>
</tr>
</tbody>
</table>

A condition without operators (other than `!`) tests for nonzero as it does in C. For example, `.WHILE (x)` is the same as `.WHILE (x != 0)`, and `.WHILE (!x)` is the same as `.WHILE (x == 0)`. You can also use the flag names (`ZERO?`, `CARRY?`, `OVERFLOW?`, `SIGN?`, and `PARITY?`) as operands in conditions with the high-level control structures. For example, in `.WHILE (CARRY?)`, the value of the carry flag determines the outcome of the condition.

Signed and Unsigned Operands

Expression operators generate unsigned jumps by default. However, if either side of the operation is signed, the assembler considers the entire operation signed.
You can use the PTR operator to tell the assembler that a particular operand in a register or constant is a signed number, as in these examples:

\[ .WHILE\ SWORD\ PTR\ [bx] \leq 0 \]
\[ .IF\ SWORD\ PTR\ mem1 > 0 \]

Without the PTR operator, the assembler would treat the contents of BX as an unsigned value.

You can also specify the size attributes of operands in memory locations with SBYTE, SWORD, and SDWORD, for use with .IF, .WHILE, and .REPEAT.

```assembly
.DATA
mem1 SBYTE ?
mem2 WORD ?
  .IF mem1 > 0
  .WHILE mem2 < bx
  .WHILE SWORD PTR ax < count
```

**Precedence Level**

As with C, you can concatenate conditions with the && operator for AND, the || operator for OR, and the ! operator for negate. The precedence level is !, &&, and ||, with ! having the highest priority. Like expressions in high-level languages, precedence is evaluated left to right.

**Expression Evaluation**

The assembler evaluates conditions created with high-level control structures according to short-circuit evaluation. If the evaluation of a particular condition automatically determines the final result (such as a condition that evaluates to false in a compound statement concatenated with AND), the evaluation does not continue.

For example, in this .WHILE statement,

\[ .WHILE (ax > 0) \&\& (WORD\ PTR\ [bx] == 0) \]

the assembler evaluates the first condition. If this condition is false (that is, if AX is less than or equal to 0), the evaluation is finished. The second condition is not checked and the loop does not execute, because a compound condition containing && requires both expressions to be true for the entire condition to be true.
Procedures

Organizing your code into procedures that execute specific tasks divides large programs into manageable units, allows for separate testing, and makes code more efficient for repetitive tasks.

Assembly-language procedures are similar to functions, subroutines, and procedures in high-level languages such as C, FORTRAN, and Pascal. Two instructions control the use of assembly-language procedures. CALL pushes the return address onto the stack and transfers control to a procedure, and RET pops the return address off the stack and returns control to that location.

The PROC and ENDP directives mark the beginning and end of a procedure. Additionally, PROC can automatically:

- Preserve register values that should not change but that the procedure might otherwise alter.
- Set up a local stack pointer, so that you can access parameters and local variables placed on the stack.
- Adjust the stack when the procedure ends.

Defining Procedures

Procedures require a label at the start of the procedure and a RET instruction at the end. Procedures are normally defined by using the PROC directive at the start of the procedure and the ENDP directive at the end. The RET instruction normally is placed immediately before the ENDP directive. The assembler makes sure the distance of the RET instruction matches the distance defined by the PROC directive. The basic syntax for PROC is:

```plaintext
label PROC [[NEAR | FAR]]

.
.
.

RET [[constant]]

label ENDP
```

The CALL instruction pushes the address of the next instruction in your code onto the stack and passes control to a specified address. The syntax is:

```plaintext
CALL {label | register | memory}
```

The operand contains a value calculated at run time. Since that operand can be a register, direct memory operand, or indirect memory operand, you can write call tables similar to the example code on page 164.
Calls can be near or far. Near calls push only the offset portion of the calling address and therefore must target a procedure within the same segment or group. You can specify the type for the target operand. If you do not, MASM uses the declared distance (NEAR or FAR) for operands that are labels and for the size of register or memory operands. The assembler then encodes the call appropriately, as it does with unconditional jumps. (See previous “Unconditional Jumps” and “Conditional Jumps.”)

MASM optimizes a call to a far non-external label when the label is in the current segment by generating the code for a near call, saving one byte.

You can define procedures without PROC and ENDP, but if you do, you must make sure that the size of the CALL matches the size of the RET. You can specify the RET instruction as RETN (Return Near) or RETF (Return Far) to override the default size:

```
call    NEAR PTR task   ; Call is declared near
        ; Return comes to here

        ; Procedure begins with near label

        ; Instructions go here

retn                    ; Return declared near
```

The syntax for RETN and RETF is:

```
label: | label LABEL NEAR
statements
RETN [[constant]]

label LABEL FAR
statements
RETF [[constant]]
```

The RET instruction (and its RETF and RETN variations) allows an optional constant operand that specifies a number of bytes to be added to the value of the SP register after the return. This operand adjusts for arguments passed to the procedure before the call, as shown in the example in “Using Local Variables,” following.

When you define procedures without PROC and ENDP, you must make sure that calls have the same size as corresponding returns. For example, RETF pops two words off the stack. If a NEAR call is made to a procedure with a far return, the popped value is meaningless, and the stack status may cause the execution to return to a random memory location, resulting in program failure.
An extended PROC syntax automates many of the details of accessing arguments and saving registers. See “Declaring Parameters with the PROC Directive,” later in this chapter.

Passing Arguments on the Stack

Each time you call a procedure, you may want it to operate on different data. This data, called “arguments,” can be passed to the procedure in various ways. Although you can pass arguments to a procedure in registers or in variables, the most common method is the stack. Microsoft languages have specific conventions for passing arguments. These conventions for assembly-language modules shared with modules from high-level languages are explained in Chapter 12, “Mixed-Language Programming.”

This section describes how a procedure accesses the arguments passed to it on the stack. Each argument is accessed as an offset from BP. However, if you use the PROC directive to declare parameters, the assembler calculates these offsets for you and lets you refer to parameters by name. The next section, “Declaring Parameters with the PROC Directive,” explains how to use PROC this way. This example shows how to pass arguments to a procedure. The procedure expects to find those arguments on the stack. As this example shows, arguments must be accessed as offsets of BP.

; C-style procedure call and definition

```
mov    ax, 10          ; Load and 
push   ax              ;   push constant as third argument
push   arg2            ; Push memory as second argument
push   cx              ; Push register as first argument
call   addup           ; Call the procedure
add    sp, 6           ; Destroy the pushed arguments
 .       ;   (equivalent to three pops)
 .
addup   PROC    NEAR            ; Return address for near call
  .   ;   takes two bytes
push   bp              ; Save base pointer - takes two bytes
  ;   so arguments start at fourth byte
mov    bp, sp          ; Load stack into base pointer
mov    ax, [bp+4]      ; Get first argument from
  ;   fourth byte above pointer
add    ax, [bp+6]      ; Add second argument from
  ;   sixth byte above pointer
add    ax, [bp+8]      ; Add third argument from
  ;   eighth byte above pointer
pop    bp              ; Restore BP
ret                     ; Return result in AX
addup   ENDP
```
Figure 7.1 shows the stack condition at key points in the process.

Starting with the 80186 processor, the ENTER and LEAVE instructions simplify the stack setup and restore instructions at the beginning and end of procedures. However, ENTER uses a lot of time. It is necessary only with nested, statically-scoped procedures. Thus, a Pascal compiler may sometimes generate ENTER. The LEAVE instruction, on the other hand, is an efficient way to do the stack cleanup. LEAVE reverses the effect of the last ENTER instruction by restoring BP and SP to their values before the procedure call.
Declaring Parameters with the PROC Directive

With the PROC directive, you can specify registers to be saved, define parameters to the procedure, and assign symbol names to parameters (rather than as offsets from BP). This section describes how to use the PROC directive to automate the parameter-accessing techniques described in the last section.

For example, the following diagram shows a valid PROC statement for a procedure called from C. It takes two parameters, var1 and arg1, and uses (and must save) the DI and SI registers:

```

The syntax for PROC is:

```

The parts of the PROC directive include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>label</td>
<td>The name of the procedure.</td>
</tr>
<tr>
<td>attributes</td>
<td>Any of several attributes of the procedure, including the distance, langtype, and visibility of the procedure. The syntax for attributes is given on the following page.</td>
</tr>
<tr>
<td>reglist</td>
<td>A list of registers following the USES keyword that the procedure uses, and that should be saved on entry. Registers in the list must be separated by blanks or tabs, not by commas. The assembler generates prologue code to push these registers onto the stack. When you exit, the assembler generates epilogue code to pop the saved register values off the stack.</td>
</tr>
<tr>
<td>parameter</td>
<td>The list of parameters passed to the procedure on the stack. The list can have a variable number of parameters. See the discussion following for the syntax of parameter. This list can be longer than one line if the continued line ends with a comma.</td>
</tr>
</tbody>
</table>

This diagram shows a valid PROC definition that uses several attributes:
## Attributes

The syntax for the attributes field is:

```
[distance] [langtype] [visibility] [<prologuearg>]
```

The explanations for these options include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>distance</td>
<td>Controls the form of the RET instruction generated. Can be NEAR or FAR. If distance is not specified, it is determined from the model declared with the .MODEL directive. NEAR distance is assumed for TINY, SMALL, COMPACT, and FLAT. The assembler assumes FAR distance for MEDIUM, LARGE, and HUG. For 80386/486 programming with 16- and 32-bit segments, you can specify NEAR16, NEAR32, FAR16, or FAR32.</td>
</tr>
<tr>
<td>langtype</td>
<td>Determines the calling convention used to access parameters and restore the stack. The BASIC, FORTRAN, and PASCAL langtypes convert procedure names to uppercase, place the last parameter in the parameter list lowest on the stack, and generate a RET num instruction to end the procedure. The RET adjusts the stack upward by num, which represents the number of bytes in the argument list. This step, called “cleaning the stack,” returns the stack pointer SP to the value it had before the caller pushed any arguments. The C and STDCALL langtype prefixes an underscore to the procedure name when the procedure’s scope is PUBLIC or EXPORT and places the first parameter lowest on the stack. SYSCALL is equivalent to the C calling convention with no underscore prefix to the procedure’s name. STDCALL uses caller stack cleanup when :VARARG is specified; otherwise the called routine must clean up the stack (see Chapter 12).</td>
</tr>
<tr>
<td>visibility</td>
<td>Indicates whether the procedure is available to other modules. The visibility can be PRIVATE, PUBLIC, or EXPORT. A procedure name is PUBLIC unless it is explicitly declared as PRIVATE. If the visibility is EXPORT, the linker places the procedure’s name in the export table for segmented executables. EXPORT also enables PUBLIC visibility. You can explicitly set the default visibility with the OPTION directive. OPTION PROC:PUBLIC sets the default to public. For more information, see Chapter 1, “Using the Option Directive.”</td>
</tr>
<tr>
<td>prologuearg</td>
<td>Specifies the arguments that affect the generation of prologue and epilogue code (the code MASM generates when it encounters a PROC directive or the end of a procedure). For an explanation of prologue and epilogue code, see “Generating Prologue and Epilogue Code,” later in this chapter.</td>
</tr>
</tbody>
</table>
Parameters

The comma that separates *parameters* from *reglist* is optional, if both fields appear on the same line. If *parameters* appears on a separate line, you must end the *reglist* field with a comma. In the syntax:

```
parmname [[tag]]
```

*parmname* is the name of the parameter. The *tag* can be the *qualifiedtype* or the keyword **VARARG**. However, only the last parameter in a list of parameters can use the **VARARG** keyword. The *qualifiedtype* is discussed in “Data Types,” Chapter 1. An example showing how to reference **VARARG** parameters appears later in this section. You can nest procedures if they do not have parameters or **USES** register lists. This diagram shows a procedure definition with one parameter definition.

The procedure presented in “Passing Arguments on the Stack,” page 182, is here rewritten using the extended **PROC** functionality. Prior to the procedure call, you must push the arguments onto the stack unless you use **INVOKE**. (See “Calling Procedures with INVOKE,” later in this chapter.)

```
addup   PROC NEAR C,
        arg1:WORD, arg2:WORD, count:WORD
        mov     ax, arg1
        add     ax, count
        add     ax, arg2
        ret
addup   ENDP
```

If the arguments for a procedure are pointers, the assembler does not generate any code to get the value or values that the pointers reference; your program must still explicitly treat the argument as a pointer. (For more information about using pointers, see Chapter 3, “Using Addresses and Pointers.”)
In the following example, even though the procedure declares the parameters as near pointers, you must code two \textbf{MOV} instructions to get the values of the parameters. The first \textbf{MOV} gets the address of the parameters, and the second \textbf{MOV} gets the parameter.

; Call from C as a \textbf{FUNCTION} returning an integer

\begin{verbatim}
.model medium c
.code
myadd proc arg1:near ptr word, arg2:near ptr word
    mov bx, arg1 ; Load first argument
    mov ax, [bx]
    mov bx, arg2 ; Add second argument
    add ax, [bx]
    ret
myadd endp
\end{verbatim}

You can use conditional-assembly directives to make sure your pointer parameters are loaded correctly for the memory model. For example, the following version of \texttt{myadd} treats the parameters as \textbf{FAR} parameters, if necessary.

\begin{verbatim}
.model medium c ; Could be any model
.code
myadd proc arg1:ptr word, arg2:ptr word
    if @datasize
        les bx, arg1 ; Far parameters
        mov ax, es:[bx]
        les bx, arg2
        add ax, es:[bx]
    else
        mov bx, arg1 ; Near parameters
        mov ax, [bx]
        mov bx, arg2
        add ax, [bx]
    endif
    ret
myadd endp
\end{verbatim}
Using VARARG

In the PROC statement, you can append the :VARARG keyword to the last parameter to indicate that the procedure accepts a variable number of arguments. However, :VARARG applies only to the C, SYSCALL, or STDCALL calling conventions (see Chapter 12). A symbol must precede :VARARG so the procedure can access arguments as offsets from the given variable name, as this example illustrates:

```assembly
addup3 PROTO NEAR C, argcount:WORD, arg1:VARARG

invoke addup3, 3, 5, 2, 4
```

```assembly
addup3 PROC NEAR C, argcount:WORD, arg1:VARARG
sub ax, ax ; Clear work register
sub si, si

.WHILE argcount > 0 ; Argcount has number of arguments
add ax, arg1[si] ; Arg1 has the first argument
dec argcount ; Point to next argument
inc si
inc si
.ENDW

ret ; Total is in AX
addup3 ENDP
```

You can pass non-default-sized pointers in the VARARG portion of the parameter list by separately passing the segment portion and the offset portion of the address.

**Note** When you use the extended PROC features and the assembler encounters a RET instruction, it automatically generates instructions to pop saved registers, remove local variables from the stack, and, if necessary, remove parameters. It generates this code for each RET instruction it encounters. You can reduce code size by having only one return and jumping to it from various locations.

Using Local Variables

In high-level languages, local variables are visible only within a procedure. In Microsoft languages, these variables are usually stored on the stack. In assembly-language programs, you can also have local variables. These variables should not be confused with labels or variable names that are local to a module, as described in Chapter 8, “Sharing Data and Procedures Among Modules and Libraries.”
This section outlines the standard methods for creating local variables. The next section shows how to use the **LOCAL** directive to make the assembler...
automatically generate local variables. When you use this directive, the assembler generates the same instructions as those demonstrated in this section but handles some of the details for you.

If your procedure has relatively few variables, you can usually write the most efficient code by placing these values in registers. Use local (stack) data when you have a large amount of temporary data for the procedure.

To use a local variable, you must save stack space for it at the start of the procedure. A procedure can then reference the variable by its position in the stack. At the end of the procedure, you must clean the stack by restoring the stack pointer. This effectively throws away all local variables and regains the stack space they occupied.

This example subtracts 2 bytes from the SP register to make room for a local word variable, then accesses the variable as [bp-2].

```assembly
push    ax         ; Push one argument
call    task      ; Call

task    PROC    NEAR
push    bp       ; Save base pointer
mov     bp, sp    ; Load stack into base pointer
sub     sp, 2     ; Save two bytes for local variable

mov     WORD PTR [bp -2], 3 ; Initialize local variable
add     ax, [bp-2] ; Add local variable to AX
sub     [bp+4], ax ; Subtract local from argument

mov     sp, bp ; Clear local variables
pop     bp ; Restore base
ret     2      ; Return result in AX and pop

task    ENDP ; two bytes to clear parameter
```

Notice the instruction mov sp, bp at the end of the procedure restores the original value of SP. The statement is required only if the value of SP changes inside the procedure (usually by allocating local variables). The argument passed to the procedure is removed with the RET instruction. Contrast this to the example in “Passing Arguments on the Stack,” page 182, in which the calling code adjusts the stack for the argument.
Figure 7.2 shows the stack at key points in the process.

Figure 7.2  Local Variables on the Stack

Creating Local Variables Automatically

MASM’s LOCAL directive automates the process for creating local variables on the stack. LOCAL frees you from having to count stack words, and it makes your code easier to write and maintain. This section illustrates the advantages of creating temporary data with the LOCAL directive.

To use the LOCAL directive, list the variables you want to create, giving a type for each one. The assembler calculates how much space is required on the stack. It also generates instructions to properly decrement SP (as described in the previous section) and to reset SP when you return from the procedure.

When you create local variables this way, your source code can refer to each local variable by name rather than as an offset of the stack pointer. Moreover,
the assembler generates debugging information for each local variable. If you have programmed before in a high-level language that allows scoping, local variables will seem familiar. For example, a C compiler sets up variables with automatic storage class in the same way as the \texttt{LOCAL} directive.

We can simplify the procedure in the previous section with the following code:

\begin{verbatim}
    task    PROC    NEAR    arg:WORD
               LOCAL   loc:WORD
         .
         .
         .
         mov     loc, 3      ; Initialize local variable
         add     ax, loc     ; Add local variable to AX
         sub     arg, ax     ; Subtract local from argument
         .                   ; Use "loc" and "arg" in other operations
         .
         ret
    task    ENDP
\end{verbatim}

The \texttt{LOCAL} directive must be on the line immediately following the \texttt{PROC} statement with the following syntax:

\texttt{LOCAL vardef [], vardef]...}

Each \texttt{vardef} defines a local variable. A local variable definition has this form:

\texttt{label[count][qualifiedtype]}

These are the parameters in local variable definitions:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{label}</td>
<td>The name given to the local variable. You can use this name to access the variable.</td>
</tr>
<tr>
<td>\texttt{count}</td>
<td>The number of elements of this name and type to allocate on the stack. You can allocate a simple array on the stack with \texttt{count}. The brackets around \texttt{count} are required. If this field is omitted, one data object is assumed.</td>
</tr>
<tr>
<td>\texttt{qualifiedtype}</td>
<td>A simple MASM type or a type defined with other types and attributes. For more information, see “Data Types” in Chapter 1.</td>
</tr>
</tbody>
</table>

If the number of local variables exceeds one line, you can place a comma at the end of the first line and continue the list on the next line. Alternatively, you can use several consecutive \texttt{LOCAL} directives.
The assembler does not initialize local variables. Your program must include code to perform any necessary initializations. For example, the following code fragment sets up a local array and initializes it to zero:

```assembly
arraysz EQU 20
aproc    PROC    USES di
    LOCAL   var1[arraysz]:WORD, var2:WORD
    ...
    ...
    ; Initialize local array to zero
    push    ss
    pop     es              ; Set ES=SS
    lea     di, var1        ; ES:DI now points to array
    mov     cx, arraysz     ; Load count
    sub     ax, ax
    rep     stosw           ; Store zeros
    ; Use the array...
    ...
    ...
    ret
aproc    ENDP
```

Even though you can reference stack variables by name, the assembler treats them as offsets of BP, and they are not visible outside the procedure. In the following procedure, `array` is a local variable.

```assembly
index   EQU   10
test    PROC  NEAR
    LOCAL   array[index]:WORD
    ...
    ...
    mov     bx, index
    ; mov    array[bx], 5 ; Not legal!
```

The second `MOV` statement may appear to be legal, but since `array` is an offset of BP, this statement is the same as

```assembly
; mov [bp + bx + arrayoffset], 5 ; Not legal!
```

BP and BX can be added only to SI and DI. This example would be legal, however, if the index value were moved to SI or DI. This type of error in your program can be difficult to find unless you keep in mind that local variables in procedures are offsets of BP.
Declaring Procedure Prototypes

MASM provides the **INVOKE** directive to handle many of the details important to procedure calls, such as pushing parameters according to the correct calling conventions. To use **INVOKE**, the procedure called must have been declared previously with a **PROC** statement, an **EXTERNDEF** (or **EXTERN**) statement, or a **TYPEDEF**. You can also place a prototype defined with **PROTO** before the **INVOKE** if the procedure type does not appear before the **INVOKE**. Procedure prototypes defined with **PROTO** inform the assembler of types and numbers of arguments so the assembler can check for errors and provide automatic conversions when **INVOKE** calls the procedure.

Declaring procedure prototypes is good programming practice, but is optional. Prototypes in MASM perform the same function as prototypes in C and other high-level languages. A procedure prototype includes the procedure name, the types, and (optionally) the names of all parameters the procedure expects. Prototypes usually are placed at the beginning of an assembly program or in a separate include file so the assembler encounters the prototype before the actual procedure.

Prototypes enable the assembler to check for unmatched parameters and are especially useful for procedures called from other modules and other languages. If you write routines for a library, you may want to put prototypes into an include file for all the procedures used in that library. For more information about using include files, see Chapter 8, “Sharing Data and Procedures among Modules and Libraries.”

The **PROTO** directive provides one way to define a procedure prototype. The syntax for a prototype definition is the same as for a procedure declaration (see “Declaring Parameters with the **PROC** Directive,” earlier in this chapter), except that you do not include the list of registers, **prologuearg** list, or the scope of the procedure.

Also, the **PROTO** keyword precedes the **langtype** and **distance** attributes. The attributes (like **C** and **FAR**) are optional. However, if they are not specified, the defaults are based on any **.MODEL** or **OPTION LANGUAGE** statement. The names of the parameters are also optional, but you must list parameter types. A label preceding **:VARARG** is also optional in the prototype but not in the **PROC** statement.

If a **PROTO** and a **PROC** for the same function appear in the same module, they must match in attribute, number of parameters, and parameter types. The easiest way to create prototypes with **PROTO** is to write your procedure and then copy the first line (the line that contains the **PROC** keyword) to a location in your program that follows the data declarations. Change **PROC** to **PROTO** and remove the **USES reglist**, the **prologuearg** field, and the **visibility** field. It
is important that the prototype follow the declarations for any types used in it to avoid any forward references used by the parameters in the prototype.

The following example illustrates how to define and then declare two typical procedures. In both prototype and declaration, the comma before the argument list is optional only when the list does not appear on a separate line:

```
; Procedure prototypes.
addup     PROTO NEAR C argcount:WORD, arg2:WORD, arg3:WORD
myproc    PROTO FAR C argcount:WORD, arg2:VARARG

; Procedure declarations
addup     PROC NEAR C, argcount:WORD, arg2:WORD, arg3:WORD.
myproc    PROC FAR C PUBLIC <callcount> USES di si,
argcount:WORD, arg2:VARARG
```

When you call a procedure with **INVOKE**, the assembler checks the arguments given by **INVOKE** against the parameters expected by the procedure. If the data types of the arguments do not match, MASM reports an error or converts the type to the expected type. These conversions are explained in the next section.

**Calling Procedures with **INVOKE**

**INVOKE** generates a sequence of instructions that push arguments and call a procedure. This helps maintain code if arguments or **langtype** for a procedure are changed. **INVOKE** generates procedure calls and automatically:

- Converts arguments to the expected types.
- Pushes arguments on the stack in the correct order.
- Cleans the stack when the procedure returns.

If arguments do not match in number or if the type is not one the assembler can convert, an error results.

If the procedure uses **VARARG**, **INVOKE** can pass a number of arguments different from the number in the parameter list without generating an error or warning. Any additional arguments must be at the end of the **INVOKE** argument list. All other arguments must match those in the prototype parameter list.
The syntax for **INVOKE** is:

**INVOKE** expression [[], arguments]]

where expression can be the procedure’s label or an indirect reference to a procedure, and arguments can be an expression, a register pair, or an expression preceded with ADDR. (The ADDR operator is discussed later in this chapter.)

Procedures with these prototypes

```plaintext
addup   PROTO NEAR C argcount:WORD, arg2:WORD, arg3:WORD
myproc  PROTO FAR C, argcount:WORD, arg2:VARARG
```

and these procedure declarations

```plaintext
addup   PROC NEAR C, argcount:WORD, arg2:WORD, arg3:WORD
myproc  PROC FAR C PUBLIC <callcount> USES di, si,
        argcount:WORD,
        arg2:VARARG
```

can be called with **INVOKE** statements like this:

```plaintext
INVOKE  addup, ax, x, y
INVOKE  myproc, bx, cx, 100, 10
```

The assembler can convert some arguments and parameter type combinations so that the correct type can be passed. The signed or unsigned qualities of the arguments in the **INVOKE** statements determine how the assembler converts them to the types expected by the procedure.

The **addup** procedure, for example, expects parameters of type **WORD**, but the arguments passed by **INVOKE** to the **addup** procedure can be any of these types:

- **BYTE, SBYTE, WORD, or SWORD**
  - An expression whose type is specified with the **PTR** operator to be one of those types
  - An 8-bit or 16-bit register
  - An immediate expression in the range –32K to +64K
  - A **NEAR PTR**

If the type is smaller than that expected by the procedure, MASM widens the argument to match.
Widening Arguments

For `INVOKE` to correctly handle type conversions, you must use the signed data types for any signed assignments. MASM widens an argument to match the type expected by a procedure’s parameters in these cases:

<table>
<thead>
<tr>
<th>Type Passed</th>
<th>Type Expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>BYTE, SBYTE</td>
<td>WORD, SWORD, DWORD, SDWORD</td>
</tr>
<tr>
<td>WORD, SWORD</td>
<td>DWORD, SDWORD</td>
</tr>
</tbody>
</table>

The assembler can extend a segment if far data is expected, and it can convert the type given in the list to the types expected. If the assembler cannot convert the type, however, it generates an error.

Detecting Errors

If the assembler needs to widen an argument, it first copies the value to AL or AX. It widens an unsigned value by placing a zero in the higher register area, and widens a signed value with a `CBW`, `CWD`, or `CWDE` instruction as required. Similarly, the assembler copies a constant argument value into AL or AX when the `.8086` directive is in effect. You can see these generated instructions in the listing file when you include the `/Sg` command-line option.

Using the accumulator register to widen or copy an argument may lead to an error if you attempt to pass AX as another argument. For example, consider the following `INVOKE` statement for a procedure with the C calling convention

```
INVOKE  myprocA, ax, cx, 100, arg
```

where `arg` is a `BYTE` variable and `myproc` expects four arguments of type `WORD`. The assembler widens and then pushes `arg` like this:

```
mov     al, DGROUP:arg
xor     ah, ah
push    ax
```

The generated code thus overwrites the last argument (AX) passed to the procedure. The assembler generates an error in this case, requiring you to rewrite the `INVOKE` statement.

To summarize, the `INVOKE` directive overwrites AX and perhaps DX when widening arguments. It also uses AX to push constants on the 8088 and 8086. If you use these registers (or EAX and EDX on an 80386/486) to pass arguments, they may be overwritten. The assembler’s error detection prevents this from ever becoming a run-time bug, but AX and DX should remain your last choice for holding arguments.
Invoking Far Addresses

You can pass a FAR pointer in a segment:offset pair, as shown in the following. Note the use of double colons to separate the register pair. The registers could be any other register pair, including a pair that an MS-DOS call uses to return values.

```asm
FPWORD   TYPEDEF FAR PTR WORD
SomeProc PROTO var1:DWORD, var2:WORD, var3:WORD

  pfaritem   FPWORD   faritem
.
.
les         bx, pfaritem
INVOKE      SomeProc, ES::BX, arg1, arg2
```

However, **INVOKE** cannot combine into a single address one argument for the segment and one for the offset.

Passing an Address

You can use the **ADDR** operator to pass the address of an expression to a procedure that expects a NEAR or FAR pointer. This example generates code to pass a far pointer (to arg1) to the procedure proc1.

```asm
PBYTE   TYPEDEF FAR PTR BYTE
arg1    BYTE    "This is a string"
proc1   PROTO   NEAR C fparg:PBYTE
.
.
INVOKE  proc1, ADDR arg1
```

For information on defining pointers with **TYPEDEF**, see “Defining Pointer Types with **TYPEDEF**” in Chapter 3.
Invoking Procedures Indirectly

You can make an indirect procedure call such as `call [bx + si]` by using a pointer to a function prototype with `TYPEDEF`, as shown in this example:

```
FUNCPROTO       TYPEDEF PROTO NEAR ARG1:WORD
FUNCPTR         TYPEDEF PTR FUNCPROTO

.DATA
pfunc   FUNCPTR OFFSET proc1, OFFSET proc2

.CODE

    mov     bx, OFFSET pfunc          ; BX points to table
    mov     si, Num                   ; Num contains 0 or 2
    INVOKE  FUNCPTR PTR [bx+si], arg1 ; Call proc1 if Num=0
           ; or proc2 if Num=2
```

You can also use `ASSUME` to accomplish the same task. The following `ASSUME` statement associates the type `FUNCPTR` with the BX register.

```
ASSUME  BX:FUNCPTR

    mov     bx, OFFSET pfunc
    mov     si, Num
    INVOKE  [bx+si], arg1
```

Checking the Code Generated

Code generated by the `INVOKE` directive may vary depending on the processor mode and calling conventions in effect. You can check your listing files to see the code generated by the `INVOKE` directive if you use the `/Sg` command-line option.

Generating Prologue and Epilogue Code

When you use the `PROC` directive with its extended syntax and argument list, the assembler automatically generates the prologue and epilogue code in your procedure. “Prologue code” is generated at the start of the procedure. It sets up a stack pointer so you can access parameters from within the procedure. It also saves space on the stack for local variables, initializes registers such as DS, and pushes registers that the procedure uses. Similarly, “epilogue code” is the code at the end of the procedure that pops registers and returns from the procedure.
The assembler automatically generates the prologue code when it encounters the first instruction or label after the `PROC` directive. This means you cannot label the prologue for the purpose of jumping to it. The assembler generates the epilogue code when it encounters a `RET` or `IRET` instruction. Using the assembler-generated prologue and epilogue code saves time and decreases the number of repetitive lines of code in your procedures.

The generated prologue or epilogue code depends on the:
- Local variables defined.
- Arguments passed to the procedure.
- Current processor selected (affects epilogue code only).
- Current calling convention.
- Options passed in the `prologuearg` of the `PROC` directive.
- Registers being saved.

The `prologuearg` list contains options specifying how to generate the prologue or epilogue code. The next section explains how to use these options, gives the standard prologue and epilogue code, and explains the techniques for defining your own prologue and epilogue code.

**Using Automatic Prologue and Epilogue Code**

The standard prologue and epilogue code handles parameters and local variables. If a procedure does not have any parameters or local variables, the prologue and epilogue code that sets up and restores a stack pointer is omitted, unless `FORCEFRAME` is included in the `prologuearg` list. (`FORCEFRAME` is discussed later in this section.) Prologue and epilogue code also generates a push and pop for each register in the register list.

The prologue code consists of three steps:

1. Point BP to top of stack.
2. Make space on stack for local variables.
3. Save registers the procedure must preserve.
The epilogue cancels these three steps in reverse order, then cleans the stack, if necessary, with a RET num instruction. For example, the procedure declaration

```
myproc  PROC NEAR PASCAL USES di, si,
         arg1:WORD, arg2:WORD, arg3:WORD
         LOCAL local1:WORD, local2:WORD
```

generates the following prologue code:

```
push    bp              ; Step 1:
mov     bp, sp          ;   point BP to stack top
sub     sp, 4           ; Step 2: space for 2 local words
push    di              ; Step 3:
push    si              ;   save registers listed in USES
```

The corresponding epilogue code looks like this:

```
pop     si              ; Undo Step 3
pop     di
mov     sp, bp          ; Undo Step 2
pop     bp              ; Undo Step 1
ret     6               ; Clean stack of pushed arguments
```

Notice the RET 6 instruction cleans the stack of the three word-sized arguments. The instruction appears in the epilogue because the procedure does not use the C calling convention. If myproc used C conventions, the epilogue would end with a RET instruction without an operand.

The assembler generates standard epilogue code when it encounters a RET instruction without an operand. It does not generate an epilogue if RET has a nonzero operand. To suppress generation of a standard epilogue, use RETN or RETF with or without an operand, or use RET 0.

The standard prologue and epilogue code recognizes two operands passed in the prologuearg list, LOADDS and FORCEFRAME. These operands modify the prologue code. Specifying LOADDS saves and initializes DS. Specifying FORCEFRAME as an argument generates a stack frame even if no arguments are sent to the procedure and no local variables are declared. If your procedure has any parameters or locals, you do not need to specify FORCEFRAME.
For example, adding `LOADDS` to the argument list for `myproc` creates this prologue:

```
push    bp              ; Step 1:
mov     bp, sp          ;   point BP to stack top
sub     sp, 4           ; Step 2: space for 2 locals
push    ds              ; Save DS and point it
mov     ax, DGROUP      ;   to DGROUP, as
mov     ds, ax          ;   instructed by LOADDS
push    di              ; Step 3:
push    si              ;   save registers listed in USES
```

The epilogue code restores DS:

```
pop     si              ; Undo Step 3
pop     di
pop     ds              ; Restore DS
mov     sp, bp          ; Undo Step 2
pop     bp              ; Undo Step 1
ret     6               ; Clean stack of pushed arguments
```

**User-Defined Prologue and Epilogue Code**

If you want a different set of instructions for prologue and epilogue code in your procedures, you can write macros that run in place of the standard prologue and epilogue code. For example, while you are debugging your procedures, you may want to include a stack check or track the number of times a procedure is called. You can write your own prologue code to do these things whenever a procedure executes. Different prologue code may also be necessary if you are writing applications for Windows. User-defined prologue macros will respond correctly if you specify `FORCEFRAME` in the `prologuearg` of a procedure.

To write your own prologue or epilogue code, the `OPTION` directive must appear in your program. It disables automatic prologue and epilogue code generation. When you specify

```
OPTION PROLOGUE : macroname
```

```
OPTION EPILOGUE : macroname
```

the assembler calls the macro specified in the `OPTION` directive instead of generating the standard prologue and epilogue code. The prologue macro must be a macro function, and the epilogue macro must be a macro procedure.
The assembler expects your prologue or epilogue macro to have this form:

```plaintext
macroname  MACRO procname, \
           flag, \
           parmbytes, \
           localbytes, \
           <reglist>, \
           userparms
```

Your macro must have formal parameters to match all the actual arguments passed. The arguments passed to your macro include:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>procname</td>
<td>The name of the procedure.</td>
</tr>
<tr>
<td>flag</td>
<td>A 16-bit flag containing the following information:</td>
</tr>
<tr>
<td></td>
<td>Bit 0, 1, 2: For calling conventions (000=unspecified language type, 001=C, 010=SYSCALL, 011=STDCALL, 100=PASCAL, 101=FORTRAN, 110=BASIC).</td>
</tr>
<tr>
<td></td>
<td>Bit 3: Undefined (not necessarily zero).</td>
</tr>
<tr>
<td></td>
<td>Bit 4: Set if the caller restores the stack (use RET, not RETn).</td>
</tr>
<tr>
<td></td>
<td>Bit 5: Set if procedure is FAR.</td>
</tr>
<tr>
<td></td>
<td>Bit 6: Set if procedure is PRIVATE.</td>
</tr>
<tr>
<td></td>
<td>Bit 7: Set if procedure is EXPORT.</td>
</tr>
<tr>
<td></td>
<td>Bit 8: Set if the epilogue is generated as a result of an IRET instruction and cleared if the epilogue is generated as a result of a RET instruction.</td>
</tr>
<tr>
<td></td>
<td>Bits 9–15: Undefined (not necessarily zero).</td>
</tr>
<tr>
<td>parmbytes</td>
<td>The accumulated count in bytes of all parameters given in the PROC statement.</td>
</tr>
<tr>
<td>localbytes</td>
<td>The count in bytes of all locals defined with the LOCAL directive.</td>
</tr>
<tr>
<td>reglist</td>
<td>A list of the registers following the USES operator in the procedure declaration. Enclose this list with angle brackets (&lt; &gt;) and separate each item with commas. Reverse the list for epilogues.</td>
</tr>
<tr>
<td>userparms</td>
<td>Any argument you want to pass to the macro. The prologuearg (if there is one) specified in the PROC directive is passed to this argument.</td>
</tr>
</tbody>
</table>

Your macro function must return the `parmbytes` parameter. However, if the prologue places other values on the stack after pushing BP and these values are not referenced by any of the local variables, the exit value must be the number of bytes for procedure locals plus any space between BP and the locals. Therefore, `parmbytes` is not always equal to the bytes occupied by the locals.
The following macro is an example of a user-defined prologue that counts the number of times a procedure is called.

```
ProfilePro     MACRO procname, flag, bytecount, numlocals, regs, macroargs
               .DATA
               procname&count  WORD 0
               .CODE
               inc     procname&count  ; Accumulates count of times the
               ;   procedure is called
               push    bp
               mov     bp, sp
               ; Other BP operations
               IFNB <regs>
                   FOR r, regs
                       push r
                   ENDM
               ENDIF
               EXITM %bytecount
               ENDM

Your program must also include this statement before calling any procedures that use the prologue:

OPTION PROLOGUE: ProfilePro
```

If you define either a prologue or an epilogue macro, the assembler uses the standard prologue or epilogue code for the one you do not define. The form of the code generated depends on the `.MODEL` and `PROC` options used.

If you want to revert to the standard prologue or epilogue code, use `PROLOGUEDEF` or `EPILOGUEDEF` as the `macroname` in the `OPTION` statement.

```
OPTION EPILOGUE: EPILOGUEDEF
```

You can completely suppress prologue or epilogue generation with

```
OPTION PROLOGUE: None
OPTION EPILOGUE: None
```

In this case, no user-defined macro is called, and the assembler does not generate a default code sequence. This state remains in effect until the next `OPTION PROLOGUE` or `OPTION EPILOGUE` is encountered.
For additional information about writing macros, see Chapter 9, “Using Macros.” The PROLOGUE.INC file provided in the MASM 6.1 distribution disks can create the prologue and epilogue sequences for the Microsoft C professional development system.

MS-DOS Interrupts

In addition to jumps, loops, and procedures that alter program execution, interrupt routines transfer execution to a different location. In this case, control goes to an interrupt routine.

You can write your own interrupt routines, either to replace an existing routine or to use an undefined interrupt number. For example, you may want to replace an MS-DOS interrupt handler, such as the Critical Error (Interrupt 24h) and CONTROL+C (Interrupt 23h) handlers. The BOUND instruction checks array bounds and calls Interrupt 5 when an error occurs. If you use this instruction, you need to write an interrupt handler for it.

This section summarizes the following:

- How to call interrupts
- How the processor handles interrupts
- How to redefine an existing interrupt routine

The example routine in this section handles addition or multiplication overflow and illustrates the steps necessary for writing an interrupt routine. For additional information about MS-DOS and BIOS interrupts, see Chapter 11, “Writing Memory-Resident Software.”

Calling MS-DOS and ROM-BIOS Interrupts

Interrupts provide a way to access MS-DOS and ROM-BIOS from assembly language. They are called with the INT instruction, which takes an immediate value between 0 and 255 as its only operand.

MS-DOS and ROM-BIOS interrupt routines accept data through registers. For instance, most MS-DOS routines (and many BIOS routines) require a function number in the AH register. Many handler routines also return values in registers. To use an interrupt, you must know what data the handler routine expects and what data, if any, it returns. For information, consult Help or one of the other references mentioned in the Introduction.
The following fragment illustrates a simple call to MS-DOS Function 9, which displays the string msg on the screen:

```
.DATA
msg BYTE "This writes to the screen$"
.CODE
mov ax, SEG msg ; Necessary only if DS does not
mov ds, ax          ;   already point to data segment
mov dx, offset msg  ; DS:DX points to msg
mov ah, 09h         ; Request Function 9
int 21h
```

When the INT instruction executes, the processor:

1. Looks up the address of the interrupt routine in the Interrupt Vector Table. This table starts at the lowest point in memory (segment 0, offset 0) and consists of a series of far pointers called vectors. Each vector comprises a 4-byte address (segment:offset) pointing to an interrupt handler routine. The table sequence implies the number of the interrupt the vector references: the first vector points to the Interrupt 0 handler, the second vector to the Interrupt 1 handler, and so forth. Thus, the vector at 0000:i*4 holds the address of the handler routine for Interrupt i.

2. Clears the trap flag (TF) and interrupt enable flag (IF).

3. Pushes the flags register, the current code segment (CS), and the current instruction pointer (IP), in that order. (The current instruction is the one following the INT statement.) As with a CALL, this ensures control returns to the next logical position in the program.

4. Jumps to the address of the interrupt routine, as specified in the Interrupt Vector Table.

5. Executes the code of the interrupt routine until it encounters an IRET instruction.

6. Pops the instruction pointer, code segment, and flags.
Figure 7.3 illustrates how interrupts work.

![Diagram of Interrupts]

**Replacing an Interrupt Routine**

To replace an existing interrupt routine, your program must:

1. Provide a new routine to handle the interrupt.
2. Replace the old routine’s address in the Interrupt Vector Table with the address of your new routine.
3. Replace the old address back into the vector table before your program ends.

You can write an interrupt routine as a procedure by using the **PROC** and **ENDP** directives. The routine should always be defined as **FAR** and should end with an **IRET** instruction instead of a **RET** instruction.
Note: You can use the full extended PROC syntax (described in “Declaring Parameters with the PROC Directive,” earlier in this chapter) to write interrupt procedures. However, you should not make interrupt procedures NEAR or specify arguments for them. You can use the USES keyword, however, to correctly generate code to save and restore a register list in interrupt procedures.

The IRET instruction in MASM 6.1 has two forms that suppress epilogue code. This allows an interrupt to have local variables or use a user-defined prologue. IRETF pops a FAR16 return address, and IRETFD pops a FAR32 return address.

The following example shows how to replace the handler for Interrupt 4. Once registered in the Interrupt Vector Table, the new routine takes control when the processor encounters either an INT 4 instruction or its special variation INTO (Interrupt on Overflow). INTO is a conditional instruction that acts only when the overflow flag is set. With INTO after a numerical calculation, your code can automatically route control to a handler routine if the calculation results in a numerical overflow. By default, the routine for Interrupt 4 simply consists of an IRET, so it returns without doing anything. Using INTO is an alternative to using JO (Jump on Overflow) to jump to another set of instructions.

The following example program first executes INT 21h to invoke MS-DOS Function 35h (Get Interrupt Vector). This function returns the existing vector for Interrupt 4. The program stores the vector, then invokes MS-DOS Function 25h (Set Interrupt Vector) to place the address of the overflow procedure in the Interrupt Vector Table. From this point on, overflow gains control whenever the processor executes INTO while the overflow flag is set. The new routine displays a message and returns with AX and DX set to 0.

```
.model large, c
.ffunc typedef far ptr
.data
msg BYTE "Overflow - result set to 0",13,10,'$'
vector FPFUNC ?
.code
.startup
mov ax, 3504h ; Load Interrupt 4 and call DOS
int 21h ; Get Interrupt Vector
mov word ptr vector[2], es ; Save segment
mov word ptr vector[0], bx ; and offset
```
push ds  ; Save DS
mov ax, cs  ; Load segment of new routine
mov ds, ax
mov dx, OFFSET ovrflow  ; Load offset of new routine
mov ax, 2504h  ; Load Interrupt 4 and call DOS
int 21h  ; Set Interrupt Vector
pop ds  ; Restore

add ax, bx  ; Do arithmetic
int 21h  ; Call Interrupt 4 if overflow

lds dx, vector  ; Load original address
mov ax, 2504h  ; Restore it to vector table
int 21h  ; with DOS set vector function
mov ax, 4C00h  ; Terminate function
int 21h

ovrflow PROC FAR
sti  ; Enable interrupts  ; (turned off by INT)
mov ah, 09h  ; Display string function
mov dx, OFFSET msg  ; Load address
int 21h  ; Call DOS
sub ax, ax  ; Set AX to 0
cwd  ; Set DX to 0
iret  ; Return
ovrflow ENDP
END

Before the program ends, it again uses MS-DOS Function 25h to reset the original Interrupt 4 vector back into the Interrupt Vector Table. This reestablishes the original routine as the handler for Interrupt 4.

The first instruction of the ovrflow routine warrants further discussion. When the processor encounters an INT instruction, it clears the interrupt flag before branching to the specified interrupt handler routine. The interrupt flag serves a crucial role in smoothing the processor’s tasks, but must not be abused. When clear, the flag inhibits hardware interrupts such as the keyboard or system timer. It should be left clear only briefly and only when absolutely necessary. Unless you have a
compelling reason to leave the flag clear, always include an STI (Set Interrupt Flag) instruction at the beginning of your interrupt handler routine to reenable hardware interrupts.

CLI (Clear Interrupt Flag) and its corollary STI are designed to protect small sections of time-dependent code from interruptions by the hardware. If you use CLI in your program, be sure to include a matching STI instruction as well. The sample interrupt handlers in Chapter 11, “Writing Memory-Resident Software,” illustrate how to use these important instructions.
CHAPTER 8

Sharing Data and Procedures Among Modules and Libraries

To use symbols and procedures in more than one module, the assembler must be able to recognize the shared data as global to all the modules where they are used. MASM provides techniques to simplify data-sharing and give a high-level interface to multiple-module programming. With these techniques, you can place shared symbols in include files. This makes the data declarations in the file available to all modules that use the include file.

This chapter explains the two data-sharing methods MASM 6.1 offers. The first method simplifies data sharing between modules with include files. The second does not involve include files. Instead, this method allows modules to share procedures and data items using the **PUBLIC** and **EXTERN** directives.

The last section of this chapter explains how to create program libraries and access their routines.

Selecting Data-Sharing Methods

If data defined in one module is to be used in other modules of a program, you must declare the data public and external. MASM provides several ways to do this:

- Declare a symbol public with the **PUBLIC** directive in the module where it is defined. This makes the symbol available to other modules. You must also place an **EXTERN** statement for that symbol in all other modules that refer to the public symbol. This statement informs the assembler that the symbol is external—that is, defined in another module.

- Declare the data communal with the **COMM** directive. However, communal variables have limitations. You cannot depend on their location in memory because they are allocated by the linker, and they cannot be initialized.

The **EXTERNDEF** directive declares a symbol either public or external, as appropriate. **EXTERNDEF** simplifies the declarations for global (public and external) variables and encourages the use of include files.
The next section provides further details on using include files. For more information on **PUBLIC** and **EXTERN**, see “Using Alternatives to Include Files,” page 219.

### Sharing Symbols with Include Files

Include files can contain any valid MASM statement, but typically consist of type and symbol declarations. The assembler inserts the contents of the include file into a module at the location of the **INCLUDE** directive. Include files are optional, but can simplify project organization by eliminating the need to insert common declarations into all modules of a program. An alternative to using include files is described in “Using Alternatives to Include Files,” page 219.

This section explains how to organize symbol definitions and the declarations that make them global (available to all modules); how to make both variables and procedures public with **EXTERNDEF**, **PROTO**, and **COMM**; and where to place these directives in the modules and include files.

### Organizing Modules

This section summarizes the organization of declarations and definitions in modules and include files and the use of the **INCLUDE** directive.

#### Include Files

Type declarations that need to be identical in every module should be placed in an include file. This ensures consistency and saves time when you update programs. Include files should contain only symbol declarations and any other declarations that are resolved at assembly time. (For a list of assembly-time operations, see “Generating and Running Executable Programs” in Chapter 1.)

If more than one module accesses the include file, the file cannot contain statements that define and allocate memory for symbols. Otherwise, the assembler would attempt to allocate the same symbol more than once.

---

**Note** An include file used in two or more modules should not allocate data variables.

---

#### Modules

An **INCLUDE** statement is usually placed before data and code segments in your modules. When the assembler encounters an **INCLUDE** directive, it opens the specified file and assembles all its statements. The assembler then returns to the original module and continues the assembly.
The **INCLUDE** directive takes the form:

```
INCLUDE filename
```

where *filename* is the full name of the include file. For example, the following declaration inserts the contents of the include file SCREEN.INC in your program:

```
INCLUDE SCREEN.INC
```

The filename in the **INCLUDE** directive must be fully specified; no extensions are assumed. If a full pathname is not given, the assembler first searches the directory of the source file containing the **INCLUDE** directive.

If the include file is not in the source file directory, the assembler searches the paths specified in the assembler’s command-line option /I, or in PWB’s Include Paths field in the MASM Option dialog box (accessed from the Option menu). The /I option takes this form:

```
/I path
```

You can include more than one /I option on the command line. The assembler then searches for include files within each specified path in the order given. If none of these directories contains the include file, the assembler finally searches in the paths specified in the **INCLUDE** environment variable. If the include file still cannot be found, an assembly error occurs. (The /x command-line option tells the assembler to ignore the **INCLUDE** environment variable when searching for include files.)

An include file may specify another include file. The assembler processes the second include file before returning to the first. Your program can nest include files this way as deeply as the amount of free memory allows.

**Include Files or Modules**

You can use the **EQU** directive to create named constants that cannot be redefined in your program. (For information about the **EQU** directive, see “Integer Constants and Constant Expressions,” page 11.) Placing a constant defined with **EQU** in an include file makes it available to all modules that use that include file.

Placing **TYPEDEF**, **STRUCT**, **UNION**, and **RECORD** definitions in an include file guarantees consistency in type definitions. If required, the variable instances derived from these definitions can be made public among the modules with **EXTERNDEF** declarations (see the next section). Macros, including macros defined with **TEXTEQU**, must be placed in include files to make them visible in other modules.
If you elect to use full segment definitions with, or instead of, simplified definitions, you can force a consistent segment order in all files by defining segments in an include file. This technique is explained in “Controlling the Segment Order,” page 47.

Declaring Symbols Public and External

It is sometimes useful to make certain procedures and variables (such as status flags) global to all program modules. Global variables are freely accessible within all routines; you do not have to explicitly pass them to the routines that need them. This section describes how to make variables and procedures global using the EXTERNDEF, PROTO, or COMM declarations within include files.

When a procedure is defined in one module and called in another module, it must be declared public in the defining module and external in the calling module(s). MASM offers three ways to declare a procedure public and external:

- Use the PUBLIC directive in the defining module and EXTERN in all other modules that reference the procedure. The PUBLIC and EXTERN directives are explained on page 220.
- Declare the procedure with EXTERNDEF.
- Prototype the procedure with the PROTO directive.

Using EXTERNDEF

MASM treats EXTERNDEF as a public declaration in the defining module, and as an external declaration in the referencing module(s). You can use the EXTERNDEF statement in your include file to make a variable common to two or more modules. EXTERNDEF works with all types of variables, including arrays, structures, unions, and records. It also works with procedures.

As a result, a single include file can contain an EXTERNDEF declaration that works in both the defining module and any referencing module. It is ignored in modules that neither define nor reference the variable. Therefore, an include file for a library which is used in multiple .EXE files does not force the definition of a symbol as EXTERN does.

The EXTERNDEF statement takes this form:

EXTERNDEF \[[langtype\] name:qualifiedtype

The name is the variable’s identifier. The qualifiedtype is explained in detail in “Data Types,” page 14.

The optional langtype specifier sets the naming conventions for the name it precedes. It overrides any language specified in the .MODEL directive. The specifier can be C, SYSCALL, STDCALL, PASCAL, FORTRAN, or
**BASIC.** For information on selecting the appropriate `langtype` type, see “Naming and Calling Conventions,” page 308.
The following diagram shows the statements that declare an array, make it public, and use it in another module.

![Diagram](image)

**Figure 8.1 Using EXTERNDEF for Variables**

The file position of `EXTERNDEF` directives is important. For more information, see “Positioning External Declarations,” following.

You can also make procedures visible by using `EXTERNDEF` without `PROTO` inside an include file. This method treats the procedure name as a simple identifier, without the parameter list, so you forgo the assembler’s ability to check for the correct parameters during assembly. Use `EXTERNDEF` with procedures in the same way as variables:

```
EXTERNDEF MyProc:FAR            ; Declare far procedure external
```

You can also use `EXTERNDEF` to make a code label global between modules so that one module can reference a label in another module. Give the label global scope with the double colon operator, like this:

```
EXTERNDEF codelabel:NEAR

   ; Declare label external
```

Another module can reference `codelabel` like this:

```
EXTERNDEF codelabel :NEAR

   jmp codelabel
```

Using PROTO

This section describes how to prototype a procedure with the PROTO directive. PROTO automatically issues an EXTERNDEF for the procedure unless the PROC statement declares the procedure PRIVATE. Defining a prototype enables type-checking for the procedure arguments.

Follow these steps to create an interface for a procedure defined in one module and called from other modules:

1. Place the PROTO declaration in the include file.
2. Define the procedure with PROC in one module. The PROC directive declares the procedure PUBLIC by default.
3. Call the procedure with the INVOKE statement (or with CALL). Make sure that all calling modules access the include file.

For descriptions, syntax, and examples of PROTO, PROC, and INVOKE, see Chapter 7, “Controlling Program Flow.”

The following example illustrates these three steps. In the example, a PROTO statement defines the far procedure CopyFile, which uses the C parameter-passing and naming conventions, and takes the arguments filename and numberlines. The diagram following the example shows the file placement for these statements.

This definition goes into the include file:

```
CopyFile PROTO FAR C filename:BYTE, numberlines:WORD
```

The procedure definition for CopyFile is:

```
CopyFile PROC FAR C USES cx, filename:BYTE, numberlines:WORD
```

To call the CopyFile procedure, you can use this INVOKE statement:

```
INVOKE CopyFile, NameVar, 200
```
Another way to share variables among modules is to add the `COMM` (communal) declaration to your include file. Since communal variables are allocated by the linker and cannot be initialized, you cannot depend on their location or sequence.

Communal variables are supported by MASM primarily for compatibility with communal variables in Microsoft C. Communal variables are not used in any other Microsoft language, and they are not compatible with C++ and some other languages.

`COMM` declares a data variable external and instructs the linker to allocate the variable if it has not been explicitly defined in a module. The memory space for communal variables may not be assigned until load time, so using communal variables may reduce the size of your executable file.

The `COMM` declaration has the syntax:

```
COMM [langtype] [NEAR | FAR] label:type[count]
```

The `label` is the name of the variable. The `langtype` sets the naming conventions for the name it precedes. It overrides any language specified in the `.MODEL` directive.
If NEAR or FAR is not specified, the variable determines the default from the current memory model (NEAR for TINY, SMALL, COMPACT, and FLAT; FAR for MEDIUM, LARGE, and HUGE). If you do not provide a memory model with the .MODEL directive, you must specify a distance when accessing a communal variable, like this:

```
mov ax, NEAR PTR CommNear
mov bx, FAR PTR CommFar
```

The type can be a constant expression, but it is usually a type such as BYTE, WORD, or DWORD, or a structure, union, or record. If you first declare the type with TYPEDEF, CodeView can provide type information. The count is the number of elements. If no count is given, one element is assumed.

The following example creates the on far variable DataBlock, which is a 1,024-element array of uninitialized signed doublewords:

```
COMM FAR DataBlock:SDWORD:1024
```

**Note** C variables declared outside functions (except static variables) are communal unless explicitly initialized; they are the same as assembly-language communal variables. If you are writing assembly-language modules for C, you can declare the same communal variables in both C and MASM include files. However, communal variables in C do not have to be declared communal in assembler. The linker will match the EXTERN, PUBLIC, and COMM statements for the variable.

EXTERNDEF (explained in the previous section) is more flexible than COMM because you can initialize variables defined with it, and your code can rely on the position and sequence of the defined data.

### Positioning External Declarations

Although LINK determines the actual address of an external symbol, the assembler assumes a default segment for the symbol, based on the location of the external directive in the source code. You should therefore position EXTERN and EXTERNDEF directives according to these rules:

- If you know which segment defines an external symbol, put the EXTERN statement in that segment.
If you know the group but not the segment, position the **EXTERN** statement outside any segment and reference the variable with the group name. For example, if `var1` is in DGROUP, reference the variable as:

```
mov DGROUP: var1, 10
```

If you know nothing about the location of an external variable, put the **EXTERN** statement outside any segment. You can use the **SEG** directive to access the external variable like this:

```
mov ax, SEG var1
mov es, ax
mov ax, es: var1
```

If the symbol is an absolute symbol or a far code label, you can declare it external anywhere in the source code.

Always close any segments opened in include files so that external declarations following an include statement are not incorrectly placed inside a segment. If you want to be certain an external definition lies outside a segment, you can use **@CurSeg**. The **@CurSeg** predefined symbol returns a blank if the definition is not in a segment. For example,

```
.DATA
.
.
@CurSeg ENDS                    ; Close segment
EXTERNDEF var:WORD
```

For information about predefined symbols such as **@CurSeg**, see “Predefined Symbols,” page 10.

### Using Alternatives to Include Files

If your project uses only two modules (or if it is written with a version of MASM prior to 6.0), you may want to continue using **PUBLIC** in the defining module and **EXTERN** in the referencing module, and not create an include file for the project. The **EXTERN** directive can be used in an include file, but the include file containing **EXTERN** cannot be added to the module that contains the corresponding **PUBLIC** directive for that symbol. This section assumes that you are not using include files.
PUBLIC and EXTERN

The PUBLIC and EXTERN directives are less flexible than EXTERNDEF and PROTO because they are module-specific: PUBLIC must appear in the defining module and EXTERN must appear in the calling modules. This section shows how to use PUBLIC and EXTERN. Information on where to place the external declarations in your file is in “Positioning External Declarations,” previous.

The PUBLIC directive makes a name visible outside the module in which it is defined. This gives other program modules access to that identifier.

The EXTERN directive performs the complementary function. It tells the assembler that a name referenced within a particular module is actually defined and declared public in another module that will be specified at link time.

A PUBLIC directive can appear anywhere in a file. Its syntax is:

```
PUBLIC [[langtype]] name, [[langtype]] name...
```

The name must be the name of an identifier defined within the current source file. Only code labels, data labels, procedures, and numeric equates can be declared public.

If you specify the langtype field here, it overrides the language specified by .MODEL. The langtype field can be C, SYSCALL, STDCALL, PASCAL, FORTRAN, or BASIC. For more information on specifying langtype types, see “Declaring Parameters with the PROC Directive,” page 184, and “Naming and Calling Conventions,” page 308.

The EXTERN directive tells the assembler that an identifier is external—defined in some other module that will be supplied at link time. Its syntax is:

```
EXTERN [[langtype]] name:{ABS | qualifiedtype}
```

“Data Types,” page 14, describes qualifiedtype. You can use the ABS (absolute) keyword only with external numeric constants. ABS causes the identifier to be imported as a relocatable unsized constant. This identifier can then be used anywhere a constant can be used. If the identifier is not found in another module at link time, the linker generates an error.
In the following example, the procedure `BuildTable` and the variable `Var` are declared public. The procedure uses the Pascal naming and data-passing conventions:

![Diagram of example](image)

**Figure 8.3 Using PUBLIC and EXTERN**

**Other Alternatives**

You can also use the directives discussed earlier (EXTERNDEF, PROTO, and COMM) without the include file. In this case, place the declarations to make a symbol global in the same module where the symbol is defined. You might want to use this technique if you are linking only a few modules that have very little data in common.

**Developing Libraries**

As you create reusable procedures, you can place them in a library file for convenient access. Although you can put any routine into a library, each library file, recognizable by its .LIB extension, usually contains related routines. For example, you might place string-manipulation functions in one library, matrix calculations in another, and port communications in another. Do not place communal variables (defined with the COMM directive) in a library.

A library consists of combined object modules, each created from a single source file. The object module is the smallest independent unit in a library. If you link with one symbol in a module, the linker adds the entire module to your program, but not the entire library.
Associating Libraries with Modules

You can choose either of two methods for associating your libraries with the modules that use them: you can use the INCLUDELIB directive inside your source files, or link the modules from the command line.

To associate a specified library with your object code, use INCLUDELIB. You can add this directive to the source file to specify the libraries you want linked, rather than specifying them in the LINK command line. The INCLUDELIB syntax is:

```
INCLUDELIB libraryname
```

The `libraryname` can be a file name or a complete path specification. If you do not specify an extension, .LIB is assumed. The `libraryname` is placed in the comment record of the object file. LINK reads this record and links with the specified library file.

For example, the statement `INCLUDELIB GRAPHICS` passes a message from the assembler to the linker telling LINK to use library routines from the file GRAPHICS.LIB. If you place this statement in the source file DRAW.ASM and GRAPHICS.LIB is in the same directory, you can assemble and link the program with the following command:

```
ML DRAW.ASM
```

Without the INCLUDELIB directive, you must link the program DRAW.ASM with either of the following commands:

```
ML DRAW.ASM GRAPHICS.LIB
ML DRAW /link GRAPHICS
```

If you want to assemble and link separately, type

```
ML /c DRAW.ASM
LINK DRAW,,,GRAPHICS
```

If you do not specify a complete path in the INCLUDELIB statement or at the command line, LINK searches for the library file in the following order:

1. In the current directory.
2. In any directories in the library field of the LINK command line.
3. In any directories specified by the LIB environment variable.

The LIB.EXE utility helps you create, organize, and maintain run-time libraries. Refer to Environment and Tools for instructions on LIB.EXE.
Using EXTERN with Library Routines

In some cases, EXTERN helps you limit the size of your executable file by specifying in the syntax an alternative name for a procedure. You would use this form of the EXTERN directive when declaring a procedure or symbol that may not need to be used.

The syntax looks like this:

```
EXTERN [[langtype]] name [[(altname)]] :qualifiedtype
```

The addition of the altname to the syntax provides the name of an alternate procedure that the linker uses to resolve the external reference if the procedure given by name is not needed. Both name and altname must have the same qualifiedtype.

When the linker encounters an external definition for a procedure that gives an altname, the linker finishes processing that module before it links the object module that contains the procedure given by name. If the program does not reference any symbols in the name file’s object from any of the linked modules, the linker uses altname to satisfy the external reference. This saves space because the library object module is not brought in.

For example, assume that the contents of STARTUP.ASM include these statements:

```
EXTERN init (dummy) : PROC

dummy PROC

    ; A procedure definition containing no executable code
    ret

dummy ENDP

call init ; Defined in FLOAT.OBJ
```

In this example, the reference to the routine init (defined in FLOAT.OBJ) does not force the module FLOAT.OBJ to be linked into the executable file. If another reference causes FLOAT.OBJ to be linked into the executable file, then init will refer to the init label in FLOAT.OBJ. If there are no references that force linkage with FLOAT.OBJ, the linker will use the alternate name for init (dummy).
CHAPTER 9

Using Macros

A “macro” is a symbolic name you give to a series of characters (a text macro) or to one or more statements (a macro procedure or function). As the assembler evaluates each line of your program, it scans the source code for names of previously defined macros. When it finds one, it substitutes the macro text for the macro name. In this way, you can avoid writing the same code several places in your program.

This chapter describes the following types of macros:

- Text macros, which expand to text within a source statement.
- Macro procedures, which expand to one or more complete statements and can optionally take parameters.
- Repeat blocks, which generate a group of statements a specified number of times or until a specified condition becomes true.
- Macro functions, which look like macro procedures and can be used like text macros but which also return a value.
- Predefined macro functions and string directives, which perform string operations.

This chapter explains how to use macros for simple code substitutions and how to write sophisticated macros with parameter lists and repeat loops. It also describes how to use these features in conjunction with local symbols, macro operators, and predefined macro functions.
Text Macros

You can give a sequence of characters a symbolic name and then use the name in place of the text later in the source code. The named text is called a text macro.

The \texttt{TEXTEQU} directive defines a text macro, as these examples show:

\begin{verbatim}
name \texttt{TEXTEQU} <text>  
name \texttt{TEXTEQU} macroId | textmacro  
name \texttt{TEXTEQU} %\texttt{constExpr}
\end{verbatim}

In the previous lines, \textit{text} is a sequence of characters enclosed in angle brackets, \textit{macroId} is a previously defined macro function, \textit{textmacro} is a previously defined text macro, and \texttt{%\texttt{constExpr}} is an expression that evaluates to text.

Here are some examples:

\begin{verbatim}
msg  \texttt{TEXTEQU} <Some text>        ; Text assigned to symbol  
string \texttt{TEXTEQU} msg            ; Text macro assigned to symbol  
msg  \texttt{TEXTEQU} <Some other text> ; New text assigned to symbol  
value \texttt{TEXTEQU} %(3 + num)      ; Text representation of resolved expression assigned to symbol
\end{verbatim}

The first line assigns text to the symbol \texttt{msg}. The second line equates the text of the \texttt{msg} text macro with a new text macro called \texttt{string}. The third line assigns new text to \texttt{msg}. Although \texttt{msg} has new text, \texttt{string} retains its original text value. The fourth line assigns 7 to \texttt{value} if \texttt{num} equals 4. If a text macro expands to another text macro (or macro function, as discussed on page 248), the resulting text macro will expand recursively.

Text macros are useful for naming strings of text that do not evaluate to integers. For example, you might use a text macro to name a floating-point constant or a bracketed expression. Here are some practical examples:

\begin{verbatim}
pi \texttt{TEXTEQU} <3.1416>           ; Floating point constant  
WPT \texttt{TEXTEQU} <WORD PTR>       ; Sequence of key words  
arg1 \texttt{TEXTEQU} [<bp+4>]        ; Bracketed expression
\end{verbatim}

Macro Procedures

If your program must perform the same task many times, you can avoid repeatedly typing the same statements each time by writing a macro procedure. Think of macro procedures (commonly called macros) as text-processing mechanisms that automatically generate repeated text.
This section uses the term “macro procedure” rather than “macro” when necessary to distinguish between a macro procedure and a macro function. Macro functions are described in “Returning Values with Macro Functions.”

Conforming to common usage, this chapter occasionally speaks of “calling” a macro, a term that deserves further scrutiny. It’s natural to think of a program calling a macro procedure in the same way it calls a normal subroutine procedure, because they seem to perform identically. However, a macro is simply a representative for real code. Wherever a macro name appears in your program, so in reality does all the code the macro represents. A macro does not cause the processor to vector off to a new location as does a normal procedure. Thus, the expression “calling a macro” may imply the effect, but does not accurately describe what actually occurs.

Creating Macro Procedures

You can define a macro procedure without parameters by placing the desired statements between the MACRO and ENDM directives:

```assembly
name    MACRO
statements
ENDM
```

For example, suppose you want a program to beep when it encounters certain errors. You could define a beep macro as follows:

```assembly
beep    MACRO
    mov  ah, 2          ;; Select DOS Print Char function
    mov  dl, 7          ;; Select ASCII 7 (bell)
    int  21h            ;; Call DOS
ENDM
```

The double semicolons mark the beginning of macro comments. Macro comments appear in a listing file only at the macro’s initial definition, not at the point where the macro is referenced and expanded. Listings are usually easier to read if the comments aren’t repeatedly expanded. However, regular comments (those with a single semicolon) are listed in macro expansions. See Appendix C for listing files and examples of how macros are expanded in listings.

Once you define a macro, you can call it anywhere in the program by using the macro’s name as a statement. The following example calls the beep macro two times if an error flag has been set.

```assembly
.IF     error   ; If error flag is true
    beep            ;   execute macro two times
    beep
.ENDF
```
During assembly, the instructions in the macro replace the macro reference. The listing file shows:

```
0017  80 3E 0000 R 00   *         cmp    error, 000h
001C  74 0C             *         je     @C0001
        beep
001E  B4 02               1         mov     ah, 2
0020  B2 07               1         mov     dl, 7
0022  CD 21               1         int     21h
        beep
0024  B4 02               1         mov     ah, 2
0026  B2 07               1         mov     dl, 7
0028  CD 21               1         int     21h
002A                  *@C0001:

Contrast this with the results of defining `beep` as a procedure using the `PROC` directive and then calling it with the `CALL` instruction.

Many such tasks can be handled as either a macro or a procedure. In deciding which method to use, you must choose between speed and size. For repetitive tasks, a procedure produces smaller code, because the instructions physically appear only once in the assembled program. However, each call to the procedure involves the additional overhead of a `CALL` and `RET` instruction. Macros do not require a change in program flow and so execute faster, but generate the same code multiple times rather than just once.

### Passing Arguments to Macros

By defining parameters for macros, you can define a general task and then execute variations of it by passing different arguments each time you call the macro. The complete syntax for a macro procedure includes a parameter list:

```
name MACRO parameterlist
statements
ENDM
```

The `parameterlist` can contain any number of parameters. Use commas to separate each parameter in the list. You cannot use reserved words as parameter names unless you disable the keyword with `OPTION NOKEYWORD`. You must also set the compatibility mode with `OPTION M510` or the `/Zm` command-line option.

To pass arguments to a macro, place the arguments after the macro name when you call the macro:

```
macroname arglist
```
The assembler treats as one item all text between matching quotation marks in an arglist.

The beep macro introduced in the previous section used the MS-DOS interrupt to write only the bell character (ASCII 7). We can rewrite the macro with a parameter that accepts any character:

```assembly
writechar MACRO char
    mov ah, 2                  ;; Select DOS Print Char function
    mov dl, char               ;; Select ASCII char
    int 21h                    ;; Call DOS
ENDM
```

Whenever it expands the macro, the assembler replaces each instance of char with the given argument value. The rewritten macro now writes any character to the screen, not just ASCII 7:

```assembly
writechar 7             ; Causes computer to beep
writechar 'A'           ; Writes A to screen
```

If you pass more arguments than there are parameters, the additional arguments generate a warning (unless you use the VARARG keyword; see page 242). If you pass fewer arguments than the macro procedure expects, the assembler assigns empty strings to the remaining parameters (unless you have specified default values). This may cause errors. For example, a reference to the writechar macro with no argument results in the following line:

```assembly
mov     dl,
```

The assembler generates an error for the expanded statement but not for the macro definition or the macro call.

You can make macros more flexible by leaving off arguments or adding additional arguments. The next section tells some of the ways your macros can handle missing or extra arguments.

### Specifying Required and Default Parameters

Macro parameters can have special attributes to make them more flexible and improve error handling. You can make parameters required, give them default values, or vary their number. Variable parameters are used almost exclusively with the FOR directive, so are covered in “FOR Loops and Variable-Length Parameters,” later in this chapter.
The syntax for a required parameter is:

```
parameter:REQ
```

For example, you can rewrite the `writechar` macro to require the `char` parameter:

```
writechar MACRO char:REQ
    mov ah, 2                  ;; Select DOS Print Char function
    mov dl, char               ;; Select ASCII char
    int 21h                    ;; Call DOS
ENDM
```

If the call does not include a matching argument, the assembler reports the error in the line that contains the macro reference. `REQ` can thus improve error reporting.

You can also accommodate missing parameters by specifying a default value, like this:

```
parameter=textvalue
```

Suppose that you often use `writechar` to beep by printing ASCII 7. The following macro definition uses an equal sign to tell the assembler to assume the parameter `char` is 7 unless you specify otherwise:

```
writechar  MACRO char:=<7>
    mov ah, 2                  ;; Select DOS Print Char function
    mov dl, char               ;; Select ASCII char
    int 21h                    ;; Call DOS
ENDM
```

If a reference to this macro does not include the argument `char`, the assembler fills in the blank with the default value of 7 and the macro beeps when called.

Enclose the default parameter value in angle brackets so the assembler recognizes the supplied value as a text value. This is explained in detail in “Text Delimiters and the Literal-Character Operator,” later in this chapter.

Missing arguments can also be handled with the `.IFB`, `.IFNB`, `.ERRB`, and `.ERRNB` directives. They are described in the section “Conditional Directives” in chapter 1 and in Help. Here is a slightly more complex macro that uses some of these techniques:
Scroll MACRO distance: REQ, attrib:=<7>, tcol, trow, bcol, brow
    IFNB <tcol> ;; Ignore arguments if blank
        mov cl, tcol
    ENDIF
    IFNB <trow>
        mov ch, trow
    ENDIF
    IFNB <bcol>
        mov dl, bcol
    ENDIF
    IFNB <brow>
        mov dh, brow
    ENDIF
    IFDIFI <attrib>, <bh>   ;; Don't move BH onto itself
        mov bh, attrib
    ENDIF
    IF distance LE 0        ;; Negative scrolls up, positive down
        mov ax, 0600h + (-(distance) AND 0FFh)
    ELSE
        mov ax, 0700h + (distance AND 0FFh)
    ENDIF
    int 10h
ENDM

In this macro, the distance parameter is required. The attrib parameter has a default value of 7 (white on black), but the macro also tests to make sure the corresponding argument isn’t BH, since it would be inefficient (though legal) to load a register onto itself. The IFNB directive is used to test for blank arguments. These are ignored to allow the user to manipulate rows and columns directly in registers CX and DX at run time.

The following shows two valid ways to call the macro:

; Assume DL and CL already loaded
dec dh
inc ch
Scroll -3 ; Scroll white on black dynamic
Scroll 5, 17h, 2, 2, 14, 12 ; Scroll white on blue constant

This macro can generate completely different code, depending on its arguments. In this sense, it is not comparable to a procedure, which always has the same code regardless of arguments.
Defining Local Symbols in Macros

You can make a symbol local to a macro by identifying it at the start of the macro with the **LOCAL** directive. Any identifier may be declared local.

You can choose whether you want numeric equates and text macros to be local or global. If a symbol will be used only inside a particular macro, you can declare it local so that the name will be available for other declarations outside the macro.

You must declare as local any labels within a macro, since a label can occur only once in the source. The **LOCAL** directive makes a special instance of the label each time the macro appears. This prevents redefinition of the label when expanding the macro. It also allows you to reuse the label elsewhere in your code.

You must declare all local symbols immediately following the **MACRO** statement (although blank lines and comments may precede the local symbol). Separate each symbol with a comma. You can attach comments to the **LOCAL** statement and list multiple **LOCAL** statements in the macro. Here is an example macro that declares local labels:

```assembly
power   MACRO   factor:REQ, exponent:REQ
    LOCAL again, gotzero      ;; Local symbols
    sub dx, dx                ;; Clear top
    mov ax, 1                 ;; Multiply by one on first loop
    mov cx, exponent          ;; Load count
    jcxz gotzero              ;; Done if zero exponent
    mov bx, factor            ;; Load factor
    again:
        mul bx                 ;; Multiply factor times exponent
    loop again
            ;; Result in AX

    gotzero:
    ENDM
```

If the labels `again` and `gotzero` were not declared local, the macro would work the first time it is called, but it would generate redefinition errors on subsequent calls. MASM implements local labels by generating different names for them each time the macro is called. You can see this in listing files. The labels in the `power` macro might be expanded to ??0000 and ??0001 on the first call and to ??0002 and ??0003 on the second.
You should avoid using anonymous labels in macros (see “Anonymous Labels” in Chapter 7). Although legal, they can produce unwanted results if you expand a macro near another anonymous label. For example, consider what happens in the following:

```
Update MACRO arg1
    .
    .
    .
    loop .
ENDM
    .
    .
    .
    jcxz 
Update ax
    .
```

Expanding `Update` places another anonymous label between the jump and its target. The line

```
jcxz 
```

consequently jumps to the start of the loop rather than over the loop—exactly the opposite of what the programmer intended.

## Assembly-Time Variables and Macro Operators

In writing macros, you will often assign and modify values assigned to symbols. Think of these symbols as assembly-time variables. Like memory variables, they are symbols that represent values. But since macros are processed at assembly time, any symbol modified in a macro must be resolved as a constant by the end of assembly.

The three kinds of assembly-time variables are:

- **Macro parameters**
- **Text macros**
- **Macro functions**

When the assembler expands a macro, it processes the symbols in the order shown here. MASM first replaces macro parameters with the text of their actual arguments, then expands text macros.
Macro parameters are similar to procedure parameters in some ways, but they also have important differences. In a procedure, a parameter has a type and a memory location. Its value can be modified within the procedure. In a macro, a parameter is a placeholder for the argument text. The value can only be assigned to another symbol or used directly; it cannot be modified. The macro may interpret the argument text it receives either as a numeric value or as a text value.

It is important to understand the difference between text values and numeric values. Numeric values can be processed with arithmetic operators and assigned to numeric equates. Text values can be processed with macro functions and assigned to text macros.

Macro operators are often helpful when processing assembly-time variables. Table 9.1 shows the macro operators that MASM provides.

### Table 9.1 MASM Macro Operators

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt; &gt;</td>
<td>Text Delimiters</td>
<td>Opens and closes a literal string.</td>
</tr>
<tr>
<td>!</td>
<td>Literal-Character Operator</td>
<td>Treats the next character as a literal character, even if it would normally have another meaning.</td>
</tr>
<tr>
<td>%</td>
<td>Expansion Operator</td>
<td>Causes the assembler to expand a constant expression or text macro.</td>
</tr>
<tr>
<td>&amp;</td>
<td>Substitution Operator</td>
<td>Tells the assembler to replace a macro parameter or text macro name with its actual value.</td>
</tr>
</tbody>
</table>

The next sections explain these operators in detail.

**Text Delimiters and the Literal-Character Operator**

The angle brackets (< >) are text delimiters. A text value is usually delimited when assigning a text macro. You can do this with TEXTSEQ, as previously shown, or with the SUBSTR and CATSTR directives discussed in “String Directives and Predefined Functions,” later in this chapter.

By delimiting the text of macro arguments, you can pass text that includes spaces, commas, semicolons, and other special characters. The following example expands a macro called work in two different ways:

```
work <1, 2, 3, 4, 5>; Passes one argument with 13 chars, including commas and spaces
work 1, 2, 3, 4, 5; Passes five arguments, each with 1 character
```
The literal-character operator (!) lets you include angle brackets as part of a delimited text value, so the assembler does not interpret them as delimiters. The assembler treats the character following ! literally rather than as a special character, like this:

```
errstr  TEXTEQU <Expression !> 255 >  ; errstr = “Expression > 255”
```

Text delimiters also have a special use with the `FOR` directive, as explained in “FOR Loops and Variable-Length Parameters,” later in this chapter.

### Expansion Operator

The expansion operator (%) expands text macros or converts constant expressions into their text representations. It performs these tasks differently in different contexts, as discussed in the following.

#### Converting Numeric Expressions to Text

The expansion operator can convert numbers to text. The operator forces immediate evaluation of a constant expression and replaces it with a text value consisting of the digits of the result. The digits are generated in the current radix (default decimal).

This application of the expansion operator is useful when defining a text macro, as the following lines show. Notice how you can enclose expressions with parentheses to make them more readable:

```
a       TEXTEQU <3 + 4>         ; a = “3 + 4”
b       TEXTEQU %3 + 4          ; b = “7”
c       TEXTEQU %(3 + 4)        ; c = “7”
```

When assigning text macros, you can use numeric equates in the constant expressions, but not text macros:

```
num     EQU     4               ; num = 4
numstr  TEXTEQU <4>             ; numstr = <4>
a       TEXTEQU %3 + num        ; a = <7>
b       TEXTEQU %3 + numstr     ; b = <7>
```

The expansion operator gives you flexibility when passing arguments to macros. It lets you pass a computed value rather than the literal text of an expression. The following example illustrates by defining a macro:

```
work    MACRO   arg
  mov ax, arg * 4
ENDM
```
which accepts different arguments:

\[
\begin{align*}
\text{work } & 2 + 3 \quad \text{; Passes "2 + 3"} \\
\text{work } & \%2 + 3 \quad \text{; Passes 5} \\
\text{work } & 2 + \text{num} \quad \text{; Passes "2 + num"} \\
\text{work } & \%2 + \text{num} \quad \text{; Passes "6"} \\
\text{work } & 2 + \text{numstr} \quad \text{; Passes "2 + numstr"} \\
\text{work } & \%2 + \text{numstr} \quad \text{; Passes "6"}
\end{align*}
\]

You must consider operator precedence when using the expansion operator. Parentheses inside the macro can force evaluation in a desired order:

\[
\begin{align*}
\text{work } & \text{ MACRO arg} \\
& \text{ mov ax, (arg) * 4} \\
& \text{ ENDM}
\end{align*}
\]

\[
\begin{align*}
\text{work } & 2 + 3 \quad \text{; Code: mov ax, (2 + 3) * 4} \\
\text{work } & \%2 + 3 \quad \text{; Code: mov ax, (5) * 4}
\end{align*}
\]

Several other uses for the expansion operator are reviewed in “Returning Values with Macro Functions,” later in this chapter.

**Expansion Operator as First Character on a Line**

The expansion operator has a different meaning when used as the first character on a line. In this case, it instructs the assembler to expand any text macros and macro functions it finds on the rest of the line.

This feature makes it possible to use text macros with directives such as `ECHO`, `TITLE`, and `SUBTITLE`, which take an argument consisting of a single text value. For instance, `ECHO` displays its argument to the standard output device during assembly. Such expansion can be useful for debugging macros and expressions, but the requirement that its argument be a single text value may have unexpected results. Consider this example:

```
ECHO Bytes per element: %SI ZEOF array / LENGTHOF array
```

Instead of evaluating the expression, this line echoes it:

```
Bytes per element: %SI ZEOF array / LENGTHOF array
```

However, you can achieve the desired result by assigning the text of the expression to a text macro and then using the expansion operator at the beginning of the line to force expansion of the text macro.
temp  TEXTEQU % (SIZEOF array / LENGTHOF array)
%  ECHO Bytes per element: temp

Note that you cannot get the same results simply by putting the % at the
beginning of the first echo line, because % expands only text macros, not
numeric equates or constant expressions.

Here are more examples of the expansion operator at the start of a line:

; Assume memmod, lang, and os specified with /D option
%  SUBTITLE Model: memmod Language: lang Operating System os

; Assume num defined earlier
tnum  TEXTEQU %num
%  .ERRE num LE 255, <Failed because tnum! > 255>

Substitution Operator

References to a parameter within a macro can sometimes be ambiguous. In such
cases, the assembler may not expand the argument as you intend. The
substitution operator (&) lets you identify unambiguously any parameter within a
macro.

As an example, consider the following macro:

errgen  MACRO num, msg
  PUBLIC errnum
  errnum BYTE "Error num: msg"
ENDM

This macro is open to several interpretations:

- Is errnum a distinct word or the word err next to the parameter num?
- Should num and msg within the string be treated literally as part of the string
  or as arguments?

In each case, the assembler chooses the most literal interpretation. That is, it
treats errnumas a distinct word, and num and msg as literal parts of the string.

The substitution operator can force different interpretations. If we rewrite the
macro with the & operator, it looks like this:

errgen  MACRO num, msg
  PUBLIC err&num
  err&num BYTE "Error &num &msg"
ENDM
When called with the following arguments,

\texttt{errgen 5, \textless Unreadable disk\textgreater}

the macro now generates this code:

\begin{verbatim}
PUBLIC err5
err5 BYTE "Error 5: Unreadable disk"
\end{verbatim}

When it encounters the \& operator, the assembler interprets subsequent text as a parameter name until the next \& or until the next separator character (such as a space, tab, or comma). Thus, the assembler correctly parses the expression \texttt{err \&num} because \texttt{num} is delimited by \& and a space. The expression could also be written as \texttt{err \&num\&}, which again unambiguously identifies \texttt{num} as a parameter.

The rule also works in reverse. You can delimit a parameter reference with \& at the end rather than at the beginning. For example, if \texttt{num} is 5, the expression \texttt{num\&12} resolves to “512.”

The assembler processes substitution operators from left to right. This can have unexpected results when you are pasting together two macro parameters. For example, if \texttt{arg1} has the value \texttt{var} and \texttt{arg2} has the value 3, you could paste them together with this statement:

\begin{verbatim}
&arg1&&arg2& BYTE "Text"
\end{verbatim}

Eliminating extra substitution operators, you might expect the following to be equivalent:

\begin{verbatim}
&arg1&arg2& BYTE "Text"
\end{verbatim}

However, this actually produces the symbol \texttt{var\&arg2}, because in processing from left to right, the assembler associates both the first and the second \& symbols with the first parameter. The assembler replaces \texttt{&arg1&} by \texttt{var}, producing \texttt{var\&arg2}. The \texttt{arg2} is never evaluated. The correct abbreviation is:

\begin{verbatim}
arg1&&arg2& BYTE "Text"
\end{verbatim}

which produces the desired symbol \texttt{var\ 3}. The symbol \texttt{arg1&\&arg2} is replaced by \texttt{var\&arg2}, which is replaced by \texttt{var\ 3}.

The substitution operator is also necessary if you want to substitute a text macro inside quotes. For example,
You can also use the substitution operator in lines beginning with the expansion operator (%) symbol, even outside macros (see page 236). It may be necessary to use the substitution operator to paste text macro names to adjacent characters or symbol names, as shown here:

```
arg    TEXTEQU <hello>
%echo  This is a string "&arg" ; Produces: This is a string "hello"
%echo  This is a string "arg"  ; Produces: This is a string "arg"
```

Macro substitution always occurs before evaluation of the high-level control structures. The assembler may therefore mistake a bit-test operator (&) in your macro for a substitution operator. You can guarantee the assembler correctly recognizes a bit-test operator by enclosing its operands in parentheses, as shown here:

```
test   MACRO   x
  .IF ax==&x      ; &x substituted with parameter value
      mov     ax, 10
  .ELSEIF ax&(x)  ; & is bitwise AND
      mov ax, 20
  .ENDIF
ENDM
```

The rules for using the substitution operator have changed significantly since MASM 5.1, making macro behavior more consistent and flexible. If you have macros written for MASM 5.1 or earlier, you can specify the old behavior by using `OLDMACROS` or `M510` with the `OPTION` directive (see page 24).

### Defining Repeat Blocks with Loop Directives

A “repeat block” is an unnamed macro defined with a loop directive. The loop directive generates the statements inside the repeat block a specified number of times or until a given condition becomes true.

MASM provides several loop directives, which let you specify the number of loop iterations in different ways. Some loop directives can also accept arguments for each iteration. Although the number of iterations is usually specified in the directive, you can use the `EXITM` directive to exit the loop early.
Repeat blocks can be used outside macros, but they frequently appear inside macro definitions to perform some repeated operation in the macro. Since repeat blocks are macros themselves, they end with the `ENDM` directive.
This section explains the following four loop directives: **REPEAT, WHILE, FOR, and FORC**. In versions of MASM prior to 6.0, **REPEAT** was called **REPT**, **FOR** was called **IRP**, and **FORC** was called **IRPC**. MASM 6.1 recognizes the old names.

The assembler evaluates repeat blocks on the first pass only. You should therefore avoid using address spans as loop counters, as in this example:

```
REPEAT (OFFSET label1 - OFFSET label2) ; Don't do this!
```

Since the distance between two labels may change on subsequent assembly passes as the assembler optimizes code, you should not assume that address spans remain constant between passes.

---

**Note** The **REPEAT** and **WHILE** directives should not be confused with the **REPEAT** and **WHILE** directives (see “Loop-Generating Directives” in Chapter 7), which generate loop and jump instructions for run-time program control.

---

### REPEAT Loops

**REPEAT** is the simplest loop directive. It specifies the number of times to generate the statements inside the macro. The syntax is:

```
REPEAT constexpr statements ENDM
```

The **constexpr** can be a constant or a constant expression, and must contain no forward references. Since the repeat block expands at assembly time, the number of iterations must be known then.

Here is an example of a repeat block used to generate data. It initializes an array containing sequential ASCII values for all uppercase letters.

```
alpha   LABEL   BYTE            ; Name the data generated
letter  =       'A'             ; Initialize counter
REPEAT  26                      ;; Repeat for each letter
        BYTE    letter              ;; Allocate ASCII code for letter
        letter  = letter + 1        ;; Increment counter
ENDM
```
Here is another use of **REPEAT**, this time inside a macro:

```assembly
beep MACRO iter:<3>
    mov ah, 2       ;; Character output function
    mov dl, 7       ;; Bell character
    REPEAT iter     ;; Repeat number specified by macro
    int 21h         ;; Call DOS
ENDM
ENDM
```

### WHILE Loops

The **WHILE** directive is similar to **REPEAT**, but the loop continues as long as a given condition is true. The syntax is:

```assembly
WHILE expression
    statements
ENDM
```

The *expression* must be a value that can be calculated at assembly time. Normally, the expression uses relational operators, but it can be any expression that evaluates to zero (false) or nonzero (true). Usually, the condition changes during the evaluation of the macro so that the loop won’t attempt to generate an infinite amount of code. However, you can use the **EXITM** directive to break out of the loop.

The following repeat block uses the **WHILE** directive to allocate variables initialized to calculated values. This is a common technique for generating lookup tables. (A lookup table is any list of precalculated results, such as a table of interest payments or trigonometric values or logarithms. Programs optimized for speed often use lookup tables, since calculating a value often takes more time than looking it up in a table.)

```assembly
cubes LABEL BYTE    ;; Name the data generated
root   =   1         ;; Initialize root
cube   =   root * root * root    ;; Calculate first cube
WHILE cube LE 32767  ;; Repeat until result too large
      WORD cube    ;; Allocate cube
      root   =   root + 1    ;; Calculate next root and cube
      cube   =   root * root * root
ENDM
```
FOR Loops and Variable-Length Parameters

With the FOR directive you can iterate through a list of arguments, working on each of them in turn. It has the following syntax:

```
FOR parameter, <argumentlist>
  statements
ENDM
```

The parameter is a placeholder that represents the name of each argument inside the FOR block. The argument list must contain comma-separated arguments and must always be enclosed in angle brackets. Here’s an example of a FOR block:

```
series  LABEL   BYTE
FOR     arg, <1, 2, 3, 4, 5, 6, 7, 8, 9, 10>
  BYTE  arg DUP (arg)
ENDM
```

On the first iteration, the arg parameter is replaced with the first argument, the value 1. On the second iteration, arg is replaced with 2. The result is an array with the first byte initialized to 1, the next 2 bytes initialized to 2, the next 3 bytes initialized to 3, and so on.

The argument list is given specifically in this example, but in some cases the list must be generated as a text macro. The value of the text macro must include the angle brackets.

```
arglist TEXTEQU <!<3, 6, 9!>> ; Generate list as text macro
%FOR  arg, arglist
  .                         ; Do something to arg
  .
ENDM
```

Note the use of the literal character operator (!) to identify angle brackets as characters, not delimiters. See “Text Delimiters (<> and the Literal-Character Operator,” earlier in this chapter.

The FOR directive also provides a convenient way to process macros with a variable number of arguments. To do this, add VARARG to the last parameter to indicate that a single named parameter will have the actual value of all additional arguments. For example, the following macro definition includes the three possible parameter attributes—required, default, and variable.

```
work    MACRO   rarg:REQ, darg:=<5>, varg:VARARG
```
The variable argument must always be last. If this macro is called with the statement

```
work 4, , 6, 7, a, b
```

the first argument is received as the value 4, the second is replaced by the default value 5, and the last four are received as the single argument `<6, 7, a, b>`. This is the same format expected by the FOR directive. The FOR directive discards leading spaces but recognizes trailing spaces.

The following macro illustrates variable arguments:

```
show MACRO chr:VARARG
    mov ah, 02h
    FOR arg, <chr>
        mov dl, arg
        int 21h
    ENDM
ENDM
```

When called with

```
show 'O', 'K', 13, 10
```

the macro displays each of the specified characters one at a time.

The parameter in a FOR loop can have the required or default attribute. You can modify the show macro to make blank arguments generate errors:

```
show MACRO chr:VARARG
    mov ah, 02h
    FOR arg:REQ, <chr>
        mov dl, arg
        int 21h
    ENDM
ENDM
```

The macro now generates an error if called with

```
show 'O', 'K', 13, 10
```
Another approach would be to use a default argument:

```assembly
show MACRO chr: VARARG
    mov ah, 02h
    FOR arg:=< ' ', <chr>
        mov dl, arg
        int 21h
    ENDM
ENDM
```

Now calling the macro with

```assembly
show 'O', 'K', 13, 10
```

inserts the default character, a space, for the blank argument.

## FORC Loops

The **FORC** directive is similar to **FOR**, but takes a string of text rather than a list of arguments. The statements are assembled once for each character (including spaces) in the string, substituting a different character for the parameter each time through.

The syntax looks like this:

```
FORC parameter, <text> statements ENDM
```

The **text** must be enclosed in angle brackets. The following example illustrates **FORC**:

```assembly
FORC arg, <ABCDEFGHIJKLMNOPQRSTUVWXYZ>
    BYTE '&arg'             ;; Allocate uppercase letter
    BYTE '&arg' + 20h       ;; Allocate lowercase letter
    BYTE '&arg' - 40h       ;; Allocate ordinal of letter
ENDM
```

Notice that the substitution operator must be used inside the quotation marks to make sure that **arg** is expanded to a character rather than treated as a literal string.

With versions of MASM earlier than 6.0, **FORC** is often used for complex parsing tasks. A long sentence can be examined character by character. Each character is then either thrown away or pasted onto a token string, depending on whether it is a separator character. The new predefined macro functions and string processing directives discussed in the following section are usually more efficient for these tasks.
String Directives and Predefined Functions

The assembler provides four directives for manipulating text:

<table>
<thead>
<tr>
<th>Directive</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>SUBSTR</td>
<td>Assigns part of string to a new symbol.</td>
</tr>
<tr>
<td>INSTR</td>
<td>Searches for one string within another.</td>
</tr>
<tr>
<td>SIZESTR</td>
<td>Determines the size of a string.</td>
</tr>
<tr>
<td>CATSTR</td>
<td>Concatenates one or more strings to a single string.</td>
</tr>
</tbody>
</table>

These directives assign a processed value to a text macro or numeric equate. For example, the following lines

```
num     =       7
newstr  CATSTR  <3 + >, %num < = > , %3 + num ; "3 + 7 = 10"
```

assign the string "3 + 7 = 10" to newstr. CATSTR and SUBSTR assign text in the same way as the TEXTEQU directive. SIZESTR and INSTR assign a number in the same way as the = operator. The four string directives take only text values as arguments. Use the expansion operator (%) when you need to make sure that constants and numeric equates expand to text, as shown in the preceding lines.

Each of the string directives has a corresponding predefined macro function version: @SubStr, @InStr, @SizeStr, and @CatStr. Macro functions are similar to the string directives, but you must enclose their arguments in parentheses. Macro functions return text values and can appear in any context where text is expected. The following section, “Returning Values with Macro Functions,” tells how to write your own macro functions. The following example is equivalent to the previous CATSTR example:

```
um     =       7
newstr  TEXTEQU @CatStr( <3 + >, %num < = > , %3 + num )
```

Macro functions are often more convenient than their directive counterparts because you can use a macro function as an argument to a string directive or to another macro function. Unlike string directives, predefined macro function names are case sensitive when you use the /Cp command-line option.

Each string directive and predefined function acts on a string, which can be any textItem. The textItem can be text enclosed in angle brackets (< >), the name of a text macro, or a constant expression preceded by % (as in %constExpr). Refer to Appendix B, “BNF Grammar,” for a list of types that textItem can represent.
The following sections summarize the syntax for each of the string directives and functions. The explanations focus on the directives, but the functions work the same except where noted.

**SUBSTR**

```
name SUBSTR string, start[, length]
```

```
@SubStr( string, start[, length] )
```

The **SUBSTR** directive assigns a substring from a given *string* to the symbol *name*. The *start* parameter specifies the position in *string*, beginning with 1, to start the substring. The *length* gives the length of the substring. If you do not specify *length*, **SUBSTR** returns the remainder of the string, including the *start* character.

**INSTR**

```
name INSTR [start] string, substring
```

```
@InStr( [start], string, substring )
```

The **INSTR** directive searches a specified *string* for an occurrence of *substring* and assigns its position number to *name*. The search is case sensitive. The *start* parameter is the position in *string* to start the search for *substring*. If you do not specify *start*, it is assumed to be position 1, the start of the string. If **INSTR** does not find *substring*, it assigns position 0 to *name*.

The **INSTR** directive assigns the position value *name* as if it were a numeric equate. In contrast, the **@InStr** returns the value as a string of digits in the current radix.

The **@InStr** function has a slightly different syntax than the **INSTR** directive. You can omit the first argument and its associated comma from the directive. You can leave the first argument blank with the function, but a blank function argument must still have a comma. For example,

```
pos     INSTR   <person>, <son>
```

is the same as

```
pos     = @InStr( , <person>, <son> )
```

You can also assign the return value to a text macro, like this:
strpos  TEXTEQU @nStr( , <person>, <son> )

**SIZESTR**

*name SIZESTR string*

@SizeStr( string )

The **SIZESTR** directive assigns the number of characters in *string* to *name*. An empty string returns a length of zero. The **SIZESTR** directive assigns the size value to a name as if it were a numeric equate. The @SizeStr function returns the value as a string of digits in the current radix.

**CATSTR**

*name CATSTR string[, string][...]*

@CatStr( string[, string][...] )

The **CATSTR** directive concatenates a list of text values into a single text value and assigns it to *name*. **TEXTEQU** is technically a synonym for **CATSTR**. **TEXTEQU** is normally used for single-string assignments, while **CATSTR** is used for multistring concatenations.

The following example pushes and pops one set of registers, illustrating several uses of string directives and functions:
; SaveRegs - Macro to generate a push instruction for each register in argument list. Saves each register name in the regpushed text macro.
regpushed TEXT EQＵ <> ; ; Initialize empty string

SaveRegs MACRO regs:VARARG
LOCAL reg
FOR reg, <regs> ;; Push each register
   push reg ;; and add it to the list
   regpushed CATSTR <reg>, < >, regpushed
ENDM ;; Strip off last comma
regpushed CATSTR < <>, regpushed ;; Mark start of list with <
regpushed SUBSTR regpushed, 1, @SizeStr( regpushed )
regpushed CATSTR regpushed, < > > ;; Mark end with >
ENDM

; RestoreRegs - Macro to generate a pop instruction for registers saved by the SaveRegs macro. Restores one group of registers.

RestoreRegs MACRO
LOCAL reg
%FOR reg, regpushed ;; Pop each register
   pop reg
ENDM
ENDM

Notice how the SaveRegs macro saves its result in the regpushed text macro for later use by the RestoreRegs macro. In this case, a text macro is used as a global variable. By contrast, the reg text macro is used only in RestoreRegs. It is declared LOCAL so it won’t take the name reg from the global name space. The MACROS.INC file provided with MASM 6.1 includes expanded versions of these same two macros.

Returning Values with Macro Functions

A macro function is a named group of statements that returns a value. When calling a macro function, you must enclose its argument list in parentheses, even if the list is empty. The function always returns text.

MASM 6.1 provides several predefined macro functions for common tasks. The predefined macros include @Environment (see page 10) and the string functions @SizeStr, @CatStr, @SubStr, and @InStr (discussed in the preceding section).

You define macro functions in exactly the same way as macro procedures, except that a macro function always returns a value through the EXITM directive. Here is an example:
DEFI NED MACRO  symbol : REQ
    l FDEF symbol
        EXITM <-1>          ;; True
    ELSE
        EXITM <0>           ;; False
    ENDIF
ENDM

This macro works like the defined operator in the C language. You can use it to test the defined state of several different symbols with a single statement, as shown here:

IF DEFINED( DOS ) AND NOT DEFINED( XENIX )
    ;; Do something
ENDIF

Notice that the macro returns integer values as strings of digits, but the IF statement evaluates numeric values or expressions. There is no conflict because the assembler sees the value returned by the macro function exactly as if the user had typed the values directly into the program:

IF -1 AND NOT 0

Returning Values with EXITM

The return value must be text, a text equate name, or the result of another macro function. A macro function must first convert a numeric value—such as a constant, a numeric equate, or the result of a numeric expression—before returning it. The macro function can use angle brackets or the expansion operator (%) to convert numbers to text. The DEFINED macro, for instance, could have returned its value as

EXITM %1

Here is another example of a macro function that uses the WHILE directive to calculate factorials:
factorial MACRO num REQ
LOCAL i, factor
factor = num
i = 1
WHILE factor GT 1
   i = i * factor
   factor = factor - 1
ENDM
EXITM %i
ENDM

The integer result of the calculation is changed to a text string with the expansion operator (%). The factorial macro can define data, as shown here:

var WORD factorial ( 4 )

This statement initializes var with the number 24 (the factorial of 4).

Using Macro Functions with Variable-Length Parameter Lists

You can use the FOR directive to handle macro parameters with the VARARG attribute. “FOR Loops and Variable-Length Parameters,” page 242, explains how to do this in simple cases where the variable parameters are handled sequentially, from first to last. However, you may sometimes need to process the parameters in reverse order or nonsequentially. Macro functions make these techniques possible.

For example, the following macro function determines the number of arguments in a VARARG parameter:

@ArgCount MACRO arglist:VARARG
LOCAL count
count = 0
FOR arg, <arglist>
   count = count + 1 ;; Count the arguments
ENDM
EXITM %count
ENDM
You can use `@ArgCount` inside a macro that has a `VARARG` parameter, as shown here:

```plaintext
work  MACRO args:VARARG
%   ECHO Number of arguments is: @ArgCount( args )
ENDM
```

Another useful task might be to select an item from an argument list using an index to indicate the item. The following macro simplifies this.

```plaintext
@ArgI MACRO index:REQ, arglist:VARARG
LOCAL count, retstr
retstr TEXTEQU <> ;; Initialize count
count  = 0 ;; Initialize return string
FOR arg, <arglist>
   count = count + 1
   IF count EQ index ;; Item is found
      retstr TEXTEQU <arg> ;; Set return string
      EXI TM ;; and exit IF
   ENDI F
ENDM
EXI TM retstr ;; Exit function
ENDM
```

You can use `@ArgI` like this:

```plaintext
work  MACRO args:VARARG
%   ECHO Third argument is: @ArgI( 3, args )
ENDM
```

Finally, you might need to process arguments in reverse order. The following macro returns a new argument list in reverse order.

```plaintext
@ArgRev MACRO arglist:REQ
LOCAL txt, arg
txt TEXTEQU <>
% FOR arg, <arglist>
txt CATSTR <arg>, <,>, txt ;; Paste each onto list
ENDM
;; Remove terminating comma
txt SUBSTR txt, 1, @SizeStr( %txt ) - 1
   txt CATSTR <!<>, txt, <!>> ;; Add angle brackets
EXI TM txt
ENDM
```
Here is an example showing @ArgRev in use:

```
work  MACRO  args:VARARG
%   FOR  arg, @ArgRev( <args> ) ;; Process in reverse order
    ECHO    arg
ENDM
ENDM
```

These three macro functions appear in the MACROS.INC include file, located on one of the MASM distribution disks.

**Expansion Operator in Macro Functions**

This list summarizes the behavior of the expansion operator (%) with macro functions.

- If a macro function is preceded by a %, it will be expanded. However, if it expands to a text macro or a macro function call, it will not expand further.
- If you use a macro function call as an argument for another macro function call, a % is not needed.
- If a macro function is called inside angle brackets and is preceded by %, it will be expanded.

**Advanced Macro Techniques**

The concept of replacing macro names with predefined macro text is simple in theory, but it has many implications and complications. Here is a brief summary of some advanced techniques you can use in macros.

**Defining Macros within Macros**

Macros can define other macros, a technique called “nesting macros.” MASM expands macros as it encounters them, so nested macros are always processed in nesting order. You cannot reference a nested macro directly in your program, since the assembler begins expansion from the outer macro. In effect, a nested macro is local to the macro that defines it. Only the amount of available memory limits the number of macros a program can nest.
The following example demonstrates how one macro can define another. The macro takes as an argument the name of a shift or rotate instruction, then creates another macro that simplifies the instruction for 8088/86 processors.

```
shifts MACRO opname                  ;; Macro generates macros
       opname& MACRO operand:REQ, rotates:=<1>
       IF rotates LE 2                 ;; One at a time is faster
          repeat rotate               ;; for 2 or less
          opname operand, 1
       END
       ELSE                            ;; Using CL is faster for
          mov cl, rotates             ;; more than 2
          opname operand, cl
       ENDIF
       ENDM
       ENDM

Recall that the 8086 processor allows only 1 or CL as an operand for shift and rotate instructions. Expanding `shifts` generates a macro for the shift instruction that uses whichever operand is more efficient. You create the entire series of macros, one for each shift instruction, like this:

```
; Call macro repeatedly to make new macros
shifts ror                     ; Generates rors
shifts rol                     ; Generates rols
shifts shr                     ; Generates shrs
shifts shl                     ; Generates shls
shifts shr                     ; Generates shrs
shifts rcl                     ; Generates rcls
shifts rcr                     ; Generates rcrs
shifts sal                     ; Generates sal s
shifts sar                     ; Generates sars
```

Then use the new macros as replacements for shift instructions, like this:

```
shrs ax, 5
rols bx, 3
```

### Testing for Argument Type and Environment

Macros can expand conditional blocks of code by testing for argument type with the `OPATTR` operator. `OPATTR` returns a single word constant that indicates the type and scope of an expression, like this:

```
OPATTR expression
```

If `expression` is not valid or is forward-referenced, `OPATTR` returns a 0. Otherwise, the return value incorporates the bit flags shown in the table below.
**OPATTR** serves as an enhanced version of the **.TYPE** operator, which returns only the low byte (bits 0–7) shown in the table. Bits 11–15 of the return value are undefined.

<table>
<thead>
<tr>
<th>Bit</th>
<th>Set If expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>References a code label</td>
</tr>
<tr>
<td>1</td>
<td>Is a memory variable or has a relocatable data label</td>
</tr>
<tr>
<td>2</td>
<td>Is an immediate value</td>
</tr>
<tr>
<td>3</td>
<td>Uses direct memory addressing</td>
</tr>
<tr>
<td>4</td>
<td>Is a register value</td>
</tr>
<tr>
<td>5</td>
<td>References no undefined symbols and is without error</td>
</tr>
<tr>
<td>6</td>
<td>Is relative to SS</td>
</tr>
<tr>
<td>7</td>
<td>References an external label</td>
</tr>
<tr>
<td>8–10</td>
<td>Has the following language type:</td>
</tr>
<tr>
<td></td>
<td>000 — No language type</td>
</tr>
<tr>
<td></td>
<td>001 — C</td>
</tr>
<tr>
<td></td>
<td>010 — SYSCALL</td>
</tr>
<tr>
<td></td>
<td>011 — STDCALL</td>
</tr>
<tr>
<td></td>
<td>100 — Pascal</td>
</tr>
<tr>
<td></td>
<td>101 — FORTRAN</td>
</tr>
<tr>
<td></td>
<td>110 — Basic</td>
</tr>
</tbody>
</table>

A macro can use **OPATTR** to determine if an argument is a constant, a register, or a memory operand. With this information, the macro can conditionally generate the most efficient code depending on argument type.

For example, given a constant argument, a macro can test it for 0. Depending on the argument’s value, the code can select the most effective method to load the value into a register:

```
IF CONST
mov     bx, CONST    ; If CONST > 0, move into BX
ELSE
sub     bx, bx       ; More efficient if CONST = 0
ENDIF
```
The second method is faster than the first, yet has the same result (with the byproduct of changing the processor flags).

The following macro illustrates some techniques using **OPATTR** by loading an address into a specified offset register:

```
load MACRO reg:REQ, adr:REQ
    IF (OPATTR (adr)) AND 00010000y   ;; Register
        IFDIFI reg, adr                ;; Don't load register
        mov    reg, adr                ;; onto itself
    ENDI F
    ELSEIF (OPATTR (adr)) AND 00000100y
        mov    reg, adr               ;; Constant
    ELSEIF (TYPE (adr) EQ BYTE) OR (TYPE (adr) EQ SBYTE)
        mov    reg, OFFSET adr         ;; Bytes
    ELSEIF (SIZE (TYPE (adr)) EQ 2
        mov    reg, adr                ;; Near pointer
    ELSEIF (SIZE (TYPE (adr)) EQ 4
        mov    reg, WORD PTR adr[0]    ;; Far pointer
        mov    ds, WORD PTR adr[2]
    ELSE
        .ERR <Illegal argument>
    ENDI F
ENDM
```

A macro also can generate different code depending on the assembly environment. The predefined text macro `@Cpu` returns a flag for processor type. The following example uses the more efficient constant variation of the **PUSH** instruction if the processor is an 80186 or higher.

```
IF  @Cpu AND 00000010y
    pushc  MACRO op             ;; 80186 or higher
        push op
    ENDM
ELSE
    pushc  MACRO op              ;; 8088/8086
        mov ax, op
        push ax
    ENDM
ENDI F
```

Another macro can now use **pushc** rather than conditionally testing for processor type itself. Although either case produces the same code, using **pushc** assembles faster because the environment is checked only once.
You can test the language and operating system using the @Interface text macro. The memory model can be tested with the @Model, @DataSize, or @CodeSize text macros.

You can save the contexts inside macros with PUSHCONTEXT and POPCONTEXT. The options for these keywords are:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASSUMES</td>
<td>Saves segment register information</td>
</tr>
<tr>
<td>RADIX</td>
<td>Saves current default radix</td>
</tr>
<tr>
<td>LISTING</td>
<td>Saves listing and CREF information</td>
</tr>
<tr>
<td>CPU</td>
<td>Saves current CPU and processor</td>
</tr>
<tr>
<td>ALL</td>
<td>All of the above</td>
</tr>
</tbody>
</table>

Using Recursive Macros

Macros can call themselves. In MASM 5.1 and earlier, recursion is an important technique for handling variable arguments. MASM 6.1 handles variable arguments much more cleanly with the FOR directive and the VARARG attribute, as described in “FOR Loops and Variable-Length Parameters,” earlier in this chapter. However, recursion is still available and may be useful for some macros.
CHAPTER 10

Writing a Dynamic-Link Library
For Windows

The Windows operating system relies heavily on service routines and data contained in special libraries called “dynamic-link libraries,” or DLLs for short. Most of what Windows comprises, from the collections of screen fonts to the routines that handle the graphical interface, is provided by DLLs. MASM 6.1 contains tools that you can use to write DLLs in assembly language. This chapter shows you how.

DLLs do not run under MS-DOS. The information in this chapter applies only to Windows, drawing in part on the chapter “Writing a Module-Definition File” in Environment and Tools. The acronym API, which appears throughout this chapter, refers to the application programming interface that Windows provides for programs. For documentation of API functions, see the Programmer’s Reference, Volume 2 of the Windows Software Development Kit (SDK).

The first section of this chapter gives an overview of DLLs and their similarities to normal libraries. The next section explores the parts of a DLL and the rules you must follow to create one. The third section applies this information to an example DLL.

Overview of DLLs

A dynamic-link library is similar to a normal run-time library. Both types of libraries contain a collection of compiled procedures, which serve one or more calling modules. To link a normal library, the linker copies the required functions from the library file (which usually has a .LIB extension) and combines them with other modules to form an executable program in .EXE format. This process is called static linking.

In dynamic linking, the library functions are not copied to an .EXE file. Instead, they reside in a separate file in executable form, ready to serve any calling program, called a “client.” When the first client requires the library, Windows takes care of loading the functions into memory and establishing linkage. If
subsequent clients also need the library, Windows dynamically links them with the proper library functions already in memory.

### Loading a DLL

How Windows loads a DLL affects the client rather than the DLL itself. Accordingly, this section focuses on how to set up a client program to use a DLL. Since the client can itself be a DLL, this is information a DLL programmer should know. However, MASM 6.1 does not provide all the tools required to create a stand-alone program for Windows. To create such a program, called an “application,” you must use tools in the Windows SDK.

Windows provides two methods for loading a dynamic-link library into memory:

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Implicit loading</td>
<td>Windows loads the DLL along with the first client program and links it before the client begins execution.</td>
</tr>
<tr>
<td>Explicit loading</td>
<td>Windows does not load the DLL until the first client explicitly requests it during execution.</td>
</tr>
</tbody>
</table>

When you write a DLL, you do not need to know beforehand which of the two methods will be used to load the library. The loading method is determined by how the client is written, not the DLL.

### Implicit Loading

The implicit method of loading a DLL offers the advantage of simplicity. The client requires no extra programming effort and can call the library functions as if they were normal run-time functions. However, implicit loading carries two constraints:

- The name of the library file must have a .DLL extension.
- You must either list all DLL functions the client calls in the IMPORTS section of the client’s module-definition file, or link the client with an import library.

An import library contains no executable code. It consists of only the names and locations of exported functions in a DLL. The linker uses the locations in the import library to resolve references to DLL functions in the client and to build an executable header. For example, the file LIBW.LIB provided with MASM 6.1 is the import library for the DLL files that contain the Windows API functions.

The IMPLIB utility described in *Environment and Tools* creates an import library. Run IMPLIB from the MS-DOS command line like this:
IMPLIB implibfile dllfile

where implibfile is the name of the import library you want to create from the DLL file dllfile. Once you have created an import library from a DLL, link it with a client program that relies on implicit loading, but does not list imported functions in its module-definition file. Continuing the preceding example, here’s the link step for a client program that calls library procedures in the DLL dllfile:

LINK client.OBJ, client.EXE, , implibfile, client.DEF

This simplified example creates the client program client.EXE, linking it with the import library implibfile, which in turn was created from the DLL file dllfile.

To summarize implicit loading, a client program must either:

- List DLL functions in the IMPORTS section of its module-definition file, or
- Link with an import library created from the DLL.

Implicit loading is best when a client always requires at least one procedure in the library, since Windows automatically loads the library with the client. If the client does not always require the library service, or if the client must choose at run time between several libraries, you should use explicit loading, discussed next.

**Explicit Loading**

To explicitly load a DLL, the client does not require linking with an import library, nor must the DLL file have an extension of .DLL. Explicit loading involves three steps in which the client calls Windows API functions:

1. The client calls **LoadLibrary** to load the DLL.
2. The client calls **GetProcAddress** to obtain the address of each DLL function it requires.
3. When finished with the DLL, the client calls **FreeLibrary** to unload the DLL from memory.

The following example fragment shows how a client written in assembly language explicitly loads a DLL called SYSINFO.DLL and calls the DLL function **GetSysDate**.

```plaintext
#include windows.inc

DATA
h_instance       HINSTANCE 0
szDLL           BYTE    'SYSINFO.DLL', 0
szDate          BYTE    'GetSysDate', 0
lpProc          DWORD   0
```

```plaintext
INCLUDE windows.inc

DATA
h_instance       HINSTANCE 0
szDLL           BYTE    'SYSINFO.DLL', 0
szDate          BYTE    'GetSysDate', 0
lpProc          DWORD   0
```
. CODE

. 

. 

INVOKE LoadLibrary, ADDR szDLL ; Load SYSINFO.DLL
mov hInstance, ax ; Save instance count
INVOKE GetProcAddress, ax, ADDR szDate ; Get and save
mov lpProc, ax ; far address of
mov lpProc[2], dx ; GetSysDate
call lpProc ; Call GetSysDate

. 

. 

INVOKE FreeLibrary, hInstance ; Unload SYSINFO.DLL

For simplicity, the above example contains no error-checking code. An actual program should check all values returned from the API functions.

The explicit method of loading a DLL requires more programming effort in the client program. However, the method allows the client to control which (if any) dynamic-link libraries to load at run time.

**Searching for a DLL File**

To load a DLL, whether implicitly or explicitly, Windows searches for the DLL file in the following directories in the order shown:

1. The current directory
2. The Windows directory, which contains WIN.COM
3. The Windows system directory, which contains system files such as GDI.EXE
4. The directory where the client program resides (except Windows 3.0 and earlier)
5. Directories listed in the PATH environment string
6. Directories mapped in a network

If Windows does not locate the DLL in any of these directories, it prompts the user with a message box.

**Building a DLL**

A DLL has additional programming requirements beyond those for a normal run-time library. This section describes the requirements pertaining to the library’s code, data, and stack. It also discusses the effects of the library’s extension name.
DLL Code

The code in a DLL consists of exported and nonexported functions. Exported functions, listed in the EXPORTS section of the module-definition file, are public routines serving clients. Nonexported functions provide private, internal support for the exported procedures. They are not visible to a client.

Under Windows, an exported library routine must appear to the caller as a far procedure. Your DLL routines can use any calling convention you wish, provided the caller assumes the same convention. You can think of dynamic-link code as code for a normal run-time library with the following additions:
- An entry procedure
- A termination procedure
- Special prologue and epilogue code

Entry Procedure

A DLL, like any Windows-based program, must have an entry procedure. Windows calls the entry procedure only once when it first loads the DLL, passing the following information in registers:
- DS contains the library’s data segment address.
- DI holds the library’s instance handle.
- CX holds the library’s heap size in bytes.

Note Windows API functions destroy all registers except DI, SI, BP, DS, and the stack pointer. To preserve the contents of other registers, your program must save the registers before an API call and restore them afterwards.

This information corresponds to the data provided to an application. Since a DLL has only one occurrence in memory, called an “instance,” the value in DI is not usually important. However, a DLL can use its instance handle to obtain resources from its own executable file.

The entry procedure does not need to record the address of the data segment. Windows automatically ensures that each exported routine in the DLL has access to the library’s data segment, as explained in “Prologue and Epilogue Code,” on page 264.

The heap size contained in CX reflects the value provided in the HEAPSIZE statement of the module-definition file. You need not make an accurate guess in the HEAPSIZE statement about the library’s heap requirements, provided you specify a moveable data segment. With a moveable segment, Windows automatically allocates more heap when needed. However, Windows can
provide no more heap in a fixed data segment than the amount specified in the 
**HEAPSIZE** statement. In any case, a library’s total heap cannot exceed 64K,
less the amount of static data. Static data and heap reside in the same segment.

Windows does not automatically deallocate unneeded heap while the DLL is in
memory. Therefore, you should not set an unnecessarily large value in the
**HEAPSIZE** statement, since doing so wastes memory.

The entry procedure calls the Windows API function **LocalInit** to allocate the
heap. The library must create a heap before its routines call any heap functions,
such as **LocalAlloc**. The following example illustrates these steps:

```
DLLEntry PROC FAR PASCAL PUBLIC ; Entry point for DLL
    j cxz   @@ ; If no heap, skip
    INVOKE LocalInit, ds, 0, cx ; Else set up the heap
    .IF     ( ax )                  ; If successful,
    .ELSE   INVOKE UnlockSegment, -1 ; unlock the data segment
    @@:    call    LibMain                 ; Call DLL's data init routine
    mov     ax, TRUE                ; Return AX = 1 if okay,
    .ENDIF                          ; else if LocalInit error,
    ret                             ; return AX = 0

DLLEntry ENDP
```

This example code is taken from the DLLENTRY.ASM module, contained in
the LIB subdirectory on one of the MASM 6.1 distribution disks. After
allocating the heap, the procedure calls the library’s initialization procedure—
called **LibMain** in this case. **LibMain** initializes the library’s static data (if
required), then returns to **DLLEntry**, which returns to Windows. If Windows
receives a return value of 0 (FALSE) from **DLLEntry**, it unloads the library and
displays an error message.

The process is similar to the way MS-DOS loads a terminate-and-stay-resident
program (TSR), described in the next chapter. Both the DLL and TSR return
control immediately to the operating system, then wait passively in memory to
be called.

The following section explains how a DLL gains control when Windows unloads
it from memory.

**Termination Procedure**

Windows maintains a DLL in memory until the last client program terminates or
explicitly unloads the library. When unloading a DLL, Windows first calls the
library’s termination procedure. This allows the DLL to return resources and do
any necessary cleanup operations before Windows unloads the library from
memory.
Libraries that have registered window procedures with `RegisterClass` need not call `UnregisterClass` to remove the class registration. Windows does this automatically when it unloads the library.

You must name the library’s termination procedure `WEP` (for Windows Exit Procedure) and list it in the `EXPORTS` section of the library’s module-definition file. To ensure immediate operation, provide an ordinal number and use the `RESIDENTNAME` keyword, as described in the chapter “Creating Module-Definition Files” in *Environment and Tools*. This keeps the name “WEP” in the Windows-resident name table at all times.

Besides its name, the code for `WEP` should also remain constantly in memory. To ensure this, place `WEP` in its own code segment and set the segment’s attributes as `PRELOAD FIXED` in the `SEGMENTS` statement of the module-definition file. Thus, your DLL code should use a memory model that allows multiple code segments, such as medium model. Since a termination procedure is usually short, keeping it resident in memory does not burden the operating system.

The termination procedure accepts a single parameter, which can have one of two values. These values are assigned to the following symbolic constants in the `WINDOWS.INC` file located in the LIB subdirectory:

- `WEP_SYSTEM_EXIT` (value 1) indicates Windows is shutting down.
- `WEP_FREE_DLL` (value 0) indicates the library’s last client has terminated or has called `FreeLibrary`, and Windows is unloading the DLL.

The following fragment provides an outline for a typical termination procedure:

```pascal
WEP PROC FAR PASCAL EXPORT
wExitCode:WORD

Prolog ; Prologue macro,
.IF wExitCode == WEP_FREE_DLL ; discussed below
 . ; Get ready to
 . ; unload
.
ELSEIF wExitCode == WEP_SYSTEM_EXIT ; Windows is
 . ; shutting down
 .
 . ENDIF ; If neither value,
 ; take no action

mov ax, TRUE ; Always return AX = 1
Epilog ; Epilogue code,
ret ; discussed below

WEP ENDP
```
Usually, the \texttt{WEP} procedure takes the same actions regardless of the parameter value, since in either case Windows will unload the DLL.

Under Windows 3.0, the \texttt{WEP} procedure receives stack space of about 256 bytes. This allows the procedure to unhook interrupts, but little else. Any other action, such as calling an API function, usually results in an unrecoverable application error because of stack overflow. Later versions of Windows provide at least 4K of stack to the \texttt{WEP} procedure, allowing it to call many API functions.

However, \texttt{WEP} should not send or post a message to a client, because the client may already be terminated. The \texttt{WEP} procedure should also not attempt file I/O, since only application processes—not DLLs—can own files. When control reaches \texttt{WEP}, the client may no longer exist and its files are closed.

\section*{Prologue and Epilogue Code}

Exported procedures in a Windows-based program require special epilogue and prologue code. (For a definition of these terms, see “Generating Prologue and Epilogue Code” in Chapter 7.) The SAMPLES subdirectory on one of the MASM 6.1 distribution disks contains macros you can use for far procedures in your Windows-based programs. Here’s a listing of the prologue macro:

\begin{verbatim}
Prolog MACRO
    mov     ax, ds          ; Must be 1st, since Windows overwrites
    nop                     ; Placeholder for 3rd byte
    inc     bp              ; Push odd BP. Not required, but
    push    bp              ; allows CodeView to recognize frame
    mov     bp, sp          ; Set up stack frame to access params
    push    ds              ; Save DS
    mov     ds, ax          ; Point DS to DLL's data segment
ENDM
\end{verbatim}

The instruction

\begin{verbatim}
    inc     bp
\end{verbatim}

marks the beginning of the stack frame with an odd number. This allows real-mode Windows to locate segment addresses on the stack and update the addresses when it moves or discards the corresponding segments. In protected mode, selector values do not change when segments are moved, so marking the stack frame is not required. However, certain debugging applications, such as Microsoft Codeview for Windows and the Microsoft Windows 80386 Debugger (both documented in \textit{Programming Tools} of the SDK), search for a marked frame to determine if the frame belongs to a far procedure. Without the mark, these debuggers give meaningless information when backtracing through the stack. Therefore, you should include the \texttt{INC BP} instruction for Windows-
based programs that may run in real mode or that require debugging with a Microsoft debugger.

Another characteristic of the prologue macro may seem puzzling at first glance. The macro moves DS into AX, then AX back into DS. This sequence of instructions lets Windows selectively overwrite the prologue code in far procedures. When Windows loads a program, it compares the names of far procedures with the list of exported procedures in the module-definition file. For procedures that do not appear on the list, Windows leaves their prologue code untouched. However, Windows overwrites the first 3 bytes of all exported procedures with

```
  mov  ax, DGROUP
```

where DGROUP represents the selector value for the library’s data segment. This explains why the prologue macro reserves the third byte with a NOP instruction. The 1-byte instruction serves as padding to provide a 3-byte area for Windows to overwrite.

The epilogue code returns BP to normal, like this:

```
Epilog MACRO
    pop ds       ; Recover original DS
    pop bp      ;   and BP+1
    dec bp      ; Reset to original BP
ENDM
```

### DLL Data

A DLL can have its own local data segment up to 64K. Besides static data, the segment contains the heap from which a procedure can allocate memory through the **LocalAlloc** API function. You should minimize static data in a DLL to reserve as much memory as possible for temporary allocations. Furthermore, all procedures in the DLL draw from the same heap space. If more than one procedure in the library accesses the heap, a procedure should not hold allocated space unnecessarily at the expense of the other procedures.

A Windows-based program must reserve a “task header” in the first 16 bytes of its data segment. If you link your program with a C run-time function, the C startup code automatically allocates the task header. Otherwise, you must explicitly reserve and initialize the header with zeros. The sample program described in “Example of a DLL:SYSINFO,” page 267, shows how to allocate a task header.
DLL Stack

A DLL does not declare a stack segment and does not allocate stack space. A client program calls a library's exported procedure through a simple far call, and the stack does not change. The procedure is, in effect, part of the calling program, and therefore uses the caller's stack.

This simple arrangement differs from that used in small and medium models, in which many C run-time functions accept near pointers as arguments. Such functions assume the pointer is relative to the current data segment. In applications, the call works even if the argument points to a local variable on the stack, since DS and SS contain the same segment address.

However, in a DLL, DS and SS point to different segments. Under small and medium models, a library procedure must always pass pointers to static variables located in the data segment, not to local variables on the stack.

When you write a DLL, include the FARSTACK keyword with the .MODEL directive, like this:

```
.MODEL small, pascal, farstack
```

This informs the assembler that SS points to a segment other than DGROUP. With full segment definitions, also add the line:

```
ASSUME DS: DGROUP, SS: NOTHING
```

DLL Extension Names

You can name an explicitly-loaded DLL file with any extension. The many files in your Windows directory with extensions such as .DRV and .FON are almost certainly DLLs. Many DLLs have an .EXE extension, though they are not true executable files.

A library with an .EXE extension should always include stub code, specified by the STUB statement in the module-definition file. The stub code activates when run under MS-DOS, usually displaying a message to inform the user that the program requires Windows. Without the stub code, the system hangs if a user attempts to run a DLL with an .EXE extension.

Do not name a DLL with a .COM extension, since MS-DOS will give control to the first byte of the program header. The header does not contain executable instructions, and the system will hang even if the DLL has stub code.

Summary

Following is a summary of the previous information in this chapter.
A dynamic-link library has only one instance — that is, it can load only once during a Windows session.

A single DLL can service calls from many client programs. Windows takes care of linkage between the DLL and each client.

Windows loads a DLL either implicitly (along with the first client) or explicitly (when the first client calls `LoadLibrary`). It unloads the DLL when the last client either terminates or calls `FreeLibrary`.

A client calls a DLL routine as a simple far procedure. The routine can use any calling convention.

Windows ensures that the first instruction in a DLL procedure moves the address of the library’s data segment into AX. You must provide the proper prologue code to allow space for this 3-byte instruction and to copy AX to DS.

All procedures in a DLL have access to a single common data segment. The segment contains both static variables and heap space, and cannot exceed 64K.

A DLL procedure uses the caller’s stack.

All exported procedures in a DLL must appear in the `EXPORTS` list in the library’s module-definition file.

**Example of a DLL: SYSINFO**

Like any library, a DLL should be as small and fast as possible — a good argument for writing it in assembly language. This section describes an example library called SYSINFO, written entirely in assembly language. The following text applies previous information in this chapter to an actual DLL.

SYSINFO contains three callable procedures. The acronym ASCIIZ refers to a string of ASCII characters terminated with a zero. The callable procedures are:

<table>
<thead>
<tr>
<th>Procedure</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>GetSysTime</td>
<td>Returns a far pointer to a 12-byte ASCIIZ string containing the current time in <em>hh:mm:ss</em> format.</td>
</tr>
<tr>
<td>GetSysDate</td>
<td>Returns a far pointer to an ASCIIZ string containing the current date in any of six languages.</td>
</tr>
<tr>
<td>GetSysInfo</td>
<td>Returns a far pointer to a structure containing the following system data:</td>
</tr>
<tr>
<td></td>
<td>• ASCIIZ string of Windows version</td>
</tr>
<tr>
<td></td>
<td>• ASCIIZ string of MS-DOS version</td>
</tr>
<tr>
<td></td>
<td>• Current keyboard status</td>
</tr>
<tr>
<td></td>
<td>• Current video mode</td>
</tr>
</tbody>
</table>
Math coprocessor flag
Processor type
ASCIIZ string of ROM-BIOS release date

To see SYSINFO in action, follow the steps below. The file SYSDATA.EXE resides in the SAMPLES\WINDLL subdirectory of MASM if you requested example files when installing MASM. Otherwise, you must first install the file with the MASM 6.1 SETUP utility.

Create SYSINFO.DLL as described in the following section and place it in the SAMPLES\WINDLL subdirectory for MASM 6.1.
From the Windows File Manager, make the SAMPLES\WINDLL subdirectory the current directory.
In the Program Manager, choose Run from the File menu and type SYSDATA
to run the example program SYSDATA.EXE. This program calls the routines in SYSINFO.DLL and displays the returned data.

Entry Routine for SYSINFO

SYSINFO links with the DLLENTRY module, which serves as the library’s entry point when Windows first loads the program. For a listing and description of DLLENTRY.ASM, see the previous section, “Entry Procedure.”

DLLENTRY replaces the LIBENTRY module provided with the Windows SDK, but unlocks the data segment after calling the API function InitTask. LIBENTRY does not unlock the segment. DLLENTRY saves some space over LIBENTRY, because it does not pass any arguments to LibMain.

The LibMain procedure handles the library’s initialization tasks. You can name the procedure whatever you want, provided you make the same change in DLLENTRY.ASM and reassemble both modules. You can even combine DLLENTRY with LibMain to form one procedure, like this:
DLLInit PROC FAR PASCAL PUBLIC ; Entry point for DLL
    jcxz @F ; If no heap, skip
    INVOKE LocalInit, ds, 0, cx ; Else set up the heap
    .IF ( ax ) ; If successful,
    INVOKE UnlockSegment, -1 ; unlock the data segment
    @@: ; Initialize DLL data. This
    ; replaces the call to the
    ; LibMain procedure.
    mov ax, TRUE ; Return AX = 1 if okay,
    .ENDIF ; else if LocalInit error,
    ret ; return AX = 0

DLLInit ENDP

Whatever you call your combined procedure (DLLInit in the preceding example), place the name on the END statement as shown. This identifies the procedure as the one that first executes when Windows loads the DLL.

SYSINFO accommodates several international languages. Currently, SYSINFO recognizes English, French, Spanish, German, Italian, and Swedish, but you can easily extend the code to include other languages. LibMain calls GetProfileString to determine the current language, then initializes the variable indx accordingly. The variable indirectly points to an array of strings containing days and months in different languages. The GetSysDate procedure uses these strings to create a full date in the correct language.

Static Data
SYSINFO stores the strings in its static data segment. This data remains in memory along with the library’s code. All procedures have equal access to the data segment.

Because the library does not call any C run-time functions, it explicitly allocates the low paragraph of the data segment with the variable TaskHead. This 16-byte area serves as the required Windows task header, described in “DLL Data,” earlier in this chapter.

Module-Definition File
The library’s module-definition file, named SYSINFO.DEF, looks like this:
LIBRARY SYSINFO
DESCRIPTION 'Sample assembly -language DLL'
EXETYPE WINDOWS
CODE PRELOAD MOVEABLE DISCARDABLE
DATA PRELOAD MOVEABLE SINGLE
SEGMENTS CODE2 PRELOAD FIXED
EXPORTS WEP RESIDENTNAME
GetSysTime @2
GetSysDate @3
GetSysInfo @4

Note the following points about the module-definition file:

- The LIBRARY statement identifies SYSINFO as a dynamic-link library.

- SYSINFO places its termination procedure WEP in a separate code segment, called CODE2, which the SEGMENTS statement declares as FIXED. This keeps the WEP routine fixed in memory, while all other code remains moveable.

- The EXPORTS section lists all procedures the library exports, including WEP.

- None of the library's procedures require heap space, so SYSINFO.DEF includes no HEAPSIZE statement.

Assembling and Linking SYSINFO
The following listing shows the description file for SYSINFO:

sysinfo.obj : sysinfo.asm dll.inc
  ML /c /W8 sysinfo.asm
dllentry.obj : dllentry.asm dll.inc.
  ML /c /W8 dllentry.asm
sysinfo.dll : dllentry.obj sysinfo.obj
  LINK dllentry sysinfo, sysinfo.dll,, libw.lib mnocrtdw.lib, sysinfo.def

To create SYSINFO.DLL, run the NMAKE utility described in Chapter 16 of Environments and Tools. Or assemble and link SYSINFO with the three command lines shown in the preceding listing. This does not require running NMAKE.

SYSINFO links with the library modules MNOCRTDW.LIB and LIBW.LIB. The first supplies the required Windows startup code for a medium-model DLL that does not use any C run-time functions. LIBW.LIB is the Windows import library, which contains no executable code. The import library provides linkage information for the Windows API functions referenced in the DLL. Windows establishes the final links when it loads the program.
Expanding SYSINFO

SYSINFO is an example of how to write an assembly-language DLL without overwhelming detail. It has plenty of room for expansion and improvements. The following list may give you some ideas:

- To create a heap area for the library, add the line

  \texttt{HEAPSIZE value}

  to the module-definition file, where value is an approximate guess for the amount of heap required in bytes. The \texttt{DLEnter} procedure automatically allocates the indicated amount of heap. Keep the data segment moveable, because Windows then provides more heap space if required by the DLL procedures.

- If you want to add a procedure that calls C run-time functions, you must replace \texttt{MNOCRTDWO.LIB} with \texttt{MDLLCW.LIB}, which is supplied with the Windows SDK. The \texttt{MDLLCW.LIB} library contains the run-time functions for medium-model DLLs.

- Each time the \texttt{GetSysInfo} procedure is called, it retrieves the version number of MS-DOS and Windows, gets the processor type, checks for a coprocessor, and reads the ROM-BIOS release date. Since this information does not change throughout a Windows session, it would be handled more efficiently in the \texttt{LibMain} procedure, which executes only once. The code is currently placed in \texttt{GetSysInfo} for the sake of clarity at the expense of efficiency.

- SYSINFO is not a true international program. You can easily add more languages, extending the \texttt{days} and \texttt{months} arrays accordingly. Moreover, for the sake of simplicity, the \texttt{GetSysDate} procedure arranges the date with an American bias. For example, in many parts of the world, the date numeral appears before the month rather than after. If you use SYSINFO in your own applications, you should include code in \texttt{LibMain} to determine the correct date format with additional calls to \texttt{GetProfileString}. You can find more information on how to do this in Chapter 18 of the Microsoft Windows \textit{Programmer's Reference, Volume 1}, supplied with the Windows SDK.
CHAPTER 11

Writing Memory-Resident Software

Through its memory-management system, MS-DOS allows a program to remain resident in memory after terminating. The resident program can later regain control of the processor to perform tasks such as background printing or “popping up” a calculator on the screen. Such a program is commonly called a TSR, from the terminate-and-stay-resident function it uses to return to MS-DOS.

This chapter explains the techniques of writing memory-resident software. The first two sections present introductory material. Following sections describe important MS-DOS and BIOS interrupts and focus on how to write safe, compatible, memory-resident software. Two example programs illustrate the techniques described in the chapter. The MASM 6.1 disks contain complete source code for the two example TSR programs.

Terminate-and-Stay-Resident Programs

MS-DOS maintains a pointer to the beginning of unused memory. Programs load into memory at this position and terminate execution by returning control to MS-DOS. Normally, the pointer remains unchanged, allowing MS-DOS to reuse the same memory when loading other programs.

A terminating program can, however, prevent other programs from loading on top of it. These programs exit to MS-DOS through the terminate-and-stay-resident function, which resets the free-memory pointer to a higher position. This leaves the program resident in a protected block of memory, even though it is no longer running.
The terminate-and-stay-resident function (Function 31h) is one of the MS-DOS services invoked through Interrupt 21h. The following fragment shows how a TSR program terminates through Function 31h and remains resident in a 1000h-byte block of memory:

```
mov     ah, 31h         ; Request DOS Function 31h
mov     al, err         ; Set return code
mov     dx, 100h        ; Reserve 100h paragraphs
                 ; (1000h bytes)
int     21h             ; Terminate-and-stay-resident
```

In current versions of MS-DOS, Interrupt 27h also provides a terminate-and-stay-resident service. However, Microsoft cannot guarantee future support for Interrupt 27h and does not recommend its use.

---

**Structure of a TSR**

TSRs consist of two distinct parts that execute at different times. The first part is the installation section, which executes only once, when MS-DOS loads the program. The installation code performs any initialization tasks required by the TSR and then exits through the terminate-and-stay-resident function.

The second part of the TSR, called the resident section, consists of code and data left in memory after termination. Though often identified with the TSR itself, the resident section makes up only part of the entire program.

The TSR’s resident code must be able to regain control of the processor and execute after the program has terminated. Methods of executing a TSR are classified as either passive or active.

---

**Passive TSRs**

The simplest way to execute a TSR is to transfer control to it explicitly from another program. Because the TSR in this case does not solicit processor control, it is said to be passive. If the calling program can determine the TSR’s memory address, it can grant control via a far jump or call. More commonly, a program activates a passive TSR through a software interrupt. The installation section of the TSR writes the address of its resident code to the proper position in the interrupt vector table (see “MS-DOS Interrupts” in Chapter 7). Any subsequent program can then execute the TSR by calling the interrupt.

Passive TSRs often replace existing software interrupts. For example, a passive TSR might replace Interrupt 10h, the BIOS video service. By intercepting calls that read or write to the screen, the TSR can access the video buffer directly, increasing display speed.
Passive TSRs allow limited access since they can be invoked only from another program. They have the advantage of executing within the context of the calling program, and thus run no risk of interfering with another process. Such a risk does exist with active TSRs.

**Active TSRs**

The second method of executing a TSR involves signaling it through some hardware event, such as a predetermined sequence of keystrokes. This type of TSR is “active” because it must continually search for its startup signal. The advantage of active TSRs lies in their accessibility. They can take control from any running application, execute, and return, all on demand.

An active TSR, however, must not seize processor control blindly. It must contain additional code that determines the proper moment at which to execute. The extra code consists of one or more routines called “interrupt handlers,” described in the following section.

**Interrupt Handlers in Active TSRs**

The memory-resident portion of an active TSR consists of two parts. One part contains the body of the TSR — the code and data that perform the program’s main tasks. The other part contains the TSR’s interrupt handlers.

An interrupt handler is a routine that takes control when a specific interrupt occurs. Although sometimes called an “interrupt service routine,” a TSR’s handler usually does not service the interrupt. Instead, it passes control to the original interrupt routine, which does the actual interrupt servicing. (See the section “Replacing an Interrupt Routine” in Chapter 7 for information on how to write an interrupt handler.)

Collectively, interrupt handlers ensure that a TSR operates compatibly with the rest of the system. Individually, each handler fulfills one or more of the following functions:

- Auditing hardware events that may signal a request for the TSR
- Monitoring system status
- Determining whether a request for the TSR should be honored, based on current system status

**Auditing Hardware Events for TSR Requests**

Active TSRs commonly use a special keystroke sequence or the timer as a request signal. A TSR invoked through one of these channels must be equipped with handlers that audit keyboard or timer events.
A keyboard handler receives control at every keystroke. It examines each key, searching for the proper signal or “hot key.” Generally, a keyboard handler should not attempt to call the TSR directly when it detects the hot key. If the TSR cannot safely interrupt the current process at that moment, the keyboard handler is forced to exit to allow the process to continue. Since the handler cannot regain control until the next keystroke, the user has to press the hot key repeatedly until the handler can comply with the request.

Instead, the handler should merely set a request flag when it detects a hot-key signal and then exit normally. Examples in the following paragraphs illustrate this technique.

For computers other than MCA (IBM PS/2 and compatible), an active TSR audits keystrokes through a handler for Interrupt 09, the keyboard interrupt:

```
Keybrd PROC FAR
    sti          ; Interrupts are okay
    push ax      ; Save AX register
    in al, 60h   ; AL = key scan code
    call CheckHotKey ; Check for hot key
    .IF carry?    ; If hot key pressed, 
      mov cs:TsrRequestFlag, TRUE ; raise flag and 
      mov cs:TsrRequestFlag, TRUE ; set up for exit
    .
.
```

A TSR running on a PS/2 computer cannot reliably read key scan codes using this method. Instead, the TSR must search for its hot key through a handler for Interrupt 15h (Miscellaneous System Services). The handler determines the current keypress from the AL register when AH equals 4Fh, as shown here:

```
MiscServ PROC FAR
    sti          ; Interrupts okay
    .IF ah == 4Fh ; If Keyboard Intercept Service:
      call CheckHotKey ; Check for hot key
      .IF carry?    ; If hot key pressed,
        mov cs:TsrRequestFlag, TRUE ; raise flag and 
        mov cs:TsrRequestFlag, TRUE ; set up for exit
    .
.
```

The example program on page 293 shows how a TSR tests for a PS/2 machine and then sets up a handler for either Interrupt 09 or Interrupt 15h to audit keystrokes.

Setting a request flag in the keyboard handler allows other code, such as the timer handler (Interrupt 08), to recognize a request for the TSR. The timer handler gains control at every timer interrupt, which occurs an average of 18.2 times per second.
The following fragment shows how a timer handler tests the request flag and continually polls until it can safely execute the TSR.

```
NewTimer PROC FAR
  ...
  cmp TsrRequestFlag, FALSE ; Has TSR been requested?
  .IF !zero?                  ; If so, can system be
    call CheckSystem          ;   interrupted safely?
  .IF carry?                  ; If so,
    call ActivateTsr          ;   activate TSR
  ...
```

**Monitoring System Status**

A TSR that uses a hardware device such as the video or disk must not interrupt while the device is active. A TSR monitors a device by handling the device’s interrupt. Each interrupt handler simply sets a flag to indicate the device is in use, and then clears the flag when the interrupt finishes.

The following shows a typical monitor handler:

```
NewHandler PROC    FAR
  mov cs:ActiveFlag, TRUE  ; Set active flag
  pushf                    ; Simulate interrupt by
  call OldHandler          ;   pushing flags, then
  mov cs:ActiveFlag, FALSE ; Clear active flag
  iret                      ; Return from interrupt
NewHandler ENDP
```

Only hardware used by the TSR requires monitoring. For example, a TSR that performs disk input/output (I/O) must monitor disk use through Interrupt 13h. The disk handler sets an active flag that prevents the TSR from executing during a read or write operation. Otherwise, the TSR’s own I/O would move the disk head. This would cause the suspended disk operation to continue with the head incorrectly positioned when the TSR returned control to the interrupted program.

In the same way, an active TSR that displays to the screen must monitor calls to Interrupt 10h. The Interrupt 10h BIOS routine does not protect critical sections of code that program the video controller. The TSR must therefore ensure it does not interrupt such nonreentrant operations.

The activities of the operating system also affect the system status. With few exceptions, MS-DOS functions are not reentrant and must not be interrupted.
However, monitoring MS-DOS is somewhat more complicated than monitoring hardware. This subject is discussed in “Using MS-DOS in Active TSRs,” later in this chapter.

Figure 11.1 illustrates the process described so far. It shows a time line for a typical TSR signaled from the keyboard. When the keyboard handler detects the proper hot key, it sets a request flag called TsrRequestFlag. Thereafter, the timer handler continually checks the system status until it can safely call the TSR.

The following comments describe the chain of events depicted in Figure 11.1. Each comment refers to one of the numbered pointers in the figure.

1. At time = t, the timer handler activates. It finds the flag TsrRequestFlag clear, indicating the user has not requested the TSR. The handler terminates without taking further action. Notice that Interrupt 13h is currently processing a disk I/O operation.

2. Before the next timer interrupt, the keyboard handler detects the hot key, signaling a request for the TSR. The keyboard handler sets TsrRequestFlag and returns.

3. At time = t + 1/18 second, the timer handler again activates and finds TsrRequestFlag set. The handler checks other active flags to determine if the TSR can safely execute. Since Interrupt 13h has not yet completed its disk operation, the timer handler finds DiskActiveFlag set. The handler therefore terminates without activating the TSR.
4. At time = t + 2/18 second, the timer handler again finds Tsr Request Flag set and repeats its scan of the active flags. Disk Active Flag is now clear, but in the interim, Interrupt 10h has activated as indicated by the flag Video Active Flag. The timer handler accordingly terminates without activating the TSR.

5. At time = t + 3/18 second, the timer handler repeats the process. This time it finds all active flags clear, indicating the TSR can safely execute. The timer handler calls the TSR, which sets its own active flag to ensure it will not interrupt itself if requested again.

6. The timer and other interrupts continue to function normally while the TSR executes.

The timer itself can serve as the startup signal if the TSR executes periodically. Screen clocks that continuously show seconds and minutes are examples of TSRs that use the timer this way. ALARM.ASM, a program described in the next section, shows another example of a timer-driven TSR.

### Determining Whether to Invoke the TSR

Once a handler receives a request signal for the TSR, it checks the various active flags maintained by the handlers that monitor system status. If any of the flags are set, the handler ignores the request and exits. If the flags are clear, the handler invokes the TSR, usually through a near or far call. Figure 11.1 illustrates how a timer handler detects a request and then periodically scans various active flags until all the flags are clear.

A TSR that changes stacks must not interrupt itself. Otherwise, the second execution would overwrite the stack data belonging to the first. A TSR prevents this by setting its own active flag before executing, as shown in Figure 11.1. A handler must check this flag along with the other active flags when determining whether the TSR can safely execute.

### Example of a Simple TSR: ALARM

This section presents a simple alarm clock TSR that demonstrates some of the material covered so far. The program accepts an argument from the command line that specifies the alarm setting in military form, such as 1635 for 4:35 P.M. For simplicity, the argument must consist of four digits, including leading zeros. To set the alarm at 7:45 A.M., for example, enter the command:

```
ALARM 0745
```

The installation section of the program begins with the Install procedure. Install computes the number of five-second intervals that must elapse before the alarm sounds and stores this number in the word Count Down. The
procedure then obtains the vector for Interrupt 08 (timer) through MS-DOS Function 35h and stores it in the far pointer OldTimer. Function 25h replaces the vector with the far address of the new timer handler NewTimer. Once installed, the new timer handler executes at every timer interrupt. These interrupts occur 18.2 times per second or 91 times every five seconds.

Each time it executes, NewTimer subtracts one from a secondary counter called Tick91. By counting 91 timer ticks, Tick91 accurately measures a period of five seconds. When Tick91 reaches zero, it’s reset to 91 and CountDown is decremented by one. When CountDown reaches zero, the alarm sounds.

;; ALARM.ASM - A simple memory-resident program that beeps the speaker
;; at a prearranged time. Can be loaded more than once for multiple
;; alarm settings. During installation, ALARM establishes a handler
;; for the timer interrupt (Interrupt 08). It then terminates through
;; the terminate and stay resident function (Function 31h). After the
;; alarm sounds, the resident portion of the program retires by setting
;; a flag that prevents further processing in the handler.

Note the following points about ALARM:

- The constant `BEEP_TONE` specifies the alarm tone. Practical values for the tone range from approximately 100 to 4,000 hertz.

- The `Install` procedure marks the beginning of the installation section of the program. Execution begins here when ALARM.COM is loaded. A TSR generally places its installation code after the resident section. This allows the terminating TSR to include the installation code with the rest of the memory it returns to MS-DOS. Since the installation section executes only once, the TSR can discard it after becoming resident.

- You can install ALARM any number of times in quick succession, each time with a new alarm setting. The timer handler does not restore the original vector for Interrupt 08 after the alarm sounds. In effect, the multiple installations remain daisy-chained in memory. The address in `OldTimer` for one installation is the address of `NewTimer` in the preceding installation.

- Until a system reboot, `NewTimer` remains in place as the Interrupt 08 handler, even after the alarm sounds. To save unnecessary activity, the byte `TimerActiveFlag` remains set after the alarm sounds. This forces an immediate jump to the original handler for all subsequent executions of `NewTimer`.

- `NewTimer` and `Sound` alter registers DS, AX, BX, CX, DX, and ES. To preserve the original values in these registers, the procedures first push them onto the stack and then restore the original values before exiting. This ensures that the process interrupted by `NewTimer` continues with valid registers after `NewTimer` returns.

- ALARM requires little stack space. It assumes the current stack is adequate and makes no attempt to set up a new one. More sophisticated TSRs, however, should as a matter of course provide their own stacks to ensure adequate stack depth. The example program presented in “Example of an Advanced TSR: SNAP,” later in this chapter, demonstrates this safety measure.
Using MS-DOS in Active TSRs

This section explains how to write active TSRs that can safely call MS-DOS functions. The material explores the problems imposed by the nonreentrant nature of MS-DOS and explains how a TSR can resolve those problems. The solution consists of four parts:

- Understanding how MS-DOS uses stacks
- Determining when MS-DOS is active
- Determining whether a TSR can safely interrupt an active MS-DOS function
- Monitoring the Critical Error flag

Understanding MS-DOS Stacks

MS-DOS functions set up their own stacks, which makes them nonreentrant. If a TSR interrupts an MS-DOS function and then executes another function that sets up the same stack, the second function will overwrite everything placed on the stack by the first function. The problem occurs when the second function returns and the first is left with unusable stack data. A TSR that calls an MS-DOS function must not interrupt any function that uses the same stack.

MS-DOS versions 2.0 and later use three internal stacks: an I/O stack, a disk stack, and an auxiliary stack. The current stack depends on the MS-DOS function. Functions 01 through 0Ch set up the I/O stack. Functions higher than 0Ch (with few exceptions) use the disk stack, as do Interrupts 25h and 26h. MS-DOS normally uses the auxiliary stack only when it executes Interrupt 24h (Critical Error Handler).

Determining MS-DOS Activity

A TSR’s handlers can determine when MS-DOS is active by consulting a 1-byte flag called the InDos flag. Every MS-DOS function sets this flag upon entry and clears it upon termination. During installation, a TSR locates the flag through Function 34h (Get Address of InDos Flag), which returns the address as ES:BX. The installation portion then stores the address so the handlers can later find the flag without again calling Function 34h.

Theoretically, a TSR can wait to execute until the InDos flag is clear, thus sidestepping the entire issue of interrupting MS-DOS. However, several low-order functions — such as Function 0Ah (Get Buffered Keyboard Input) — wait idly for an expected keystroke before they terminate. If a TSR were allowed to execute only after MS-DOS returned, it too would have to wait for the terminating event.
The solution lies in determining when the low-order functions 01 through 0Ch are active. MS-DOS provides another service for this purpose: Interrupt 28h, the Idle Interrupt.

**Interrupting MS-DOS Functions**

MS-DOS continually calls Interrupt 28h from the low-order polling functions as they wait for keyboard input. This signal says that MS-DOS is idle and that a TSR may interrupt provided it does not overwrite the I/O stack. Put another way, a TSR can safely interrupt MS-DOS Functions 01 through 0Ch provided it does not call them.

An active TSR that calls MS-DOS must monitor Interrupt 28h with a handler. When the handler gains control, it checks the TSR request flag. If the flag indicates the TSR has been requested and if system hardware is inactive, the handler executes the TSR. Since control must eventually return to the idle MS-DOS function which has stored data on the I/O stack, the TSR in this case must not call any MS-DOS function that also uses the I/O stack. Table 11.1 shows which functions set up the I/O stack for various versions of MS-DOS.

* I/O=I/O stack, Aux = auxiliary stack, Disk = disk stack, Caller = caller’s stack, n/a = function not available.
TSRs that perform tasks of long or indefinite duration should themselves call Interrupt 28h. For example, a TSR that polls for keyboard input should include an INT 28h instruction in the polling loop, as shown here:

```
poll:    int     28h          ; Signal idle state
        mov     ah, 1
        int     16h          ; Key waiting?
        jnz     poll         ; If not, repeat polling loop
        sub     ah, ah
        int     16h          ; Otherwise, get key
```

This courtesy gives other TSRs a chance to execute if the InDos flag happens to be set.

**Monitoring the Critical Error Flag**

MS-DOS sets the Critical Error flag to a nonzero value when it detects a critical error. It then invokes Interrupt 24h (Critical Error Handler) and clears the flag when Interrupt 24h returns. MS-DOS functions higher than 0Ch are illegal during critical error processing. Therefore, a TSR that calls MS-DOS must not execute while the Critical Error flag is set.

MS-DOS versions 3.1 and later locate the Critical Error flag in the byte preceding the InDos flag. A single call to Function 34h (Get Address of InDos Flag) thus effectively returns the addresses of both flags. For earlier versions of MS-DOS or for the compatibility version of MS-DOS in OS/2 1.x, a TSR must call Function 34h and then scan the segment returned in the ES register for one of the two following sequences of instructions:

```
; Sequence of instructions in DOS Versions 2.0 - 3.0
    cmp     ss:[CriticalErrorFlag], 0
    jne     @F
    int     28h

; Sequence of instructions in DOS compatibility version for OS/2 1.x
    test    [CriticalErrorFlag], 0FFh
    jnz     @F
    push    ss:[ ? ]
    int     28h
```

The question mark inside brackets in the preceding **PUSH** statement indicates that the operand for the **PUSH** instruction can be any legal operand.

In either version of MS-DOS, the operand field in the first instruction gives the flag’s offset. The value in ES determines the segment address. “Example of an Advanced TSR: SNAP,” later in the chapter, presents a program that shows how to locate the Critical Error flag with this technique.
Preventing Interference

This section describes how an active TSR can avoid interfering with the process it interrupts. Interference occurs when a TSR commits an error or performs an action that affects the interrupted process after the TSR returns. Examples of interference range from relatively harmless, such as moving the cursor, to serious, such as overrunning a stack.

Although a TSR can interfere with another process in many different ways, protection against interference involves only three steps:

1. Recording a current configuration
2. Changing the configuration so it applies to the TSR
3. Restoring the original configuration before terminating

The example program described on page 293 demonstrates all the noninterference safeguards described in this section. These safeguards by no means exhaust the subject of noninterference. More sophisticated TSRs may require more sophisticated methods. However, noninterference methods generally fall into one of the following categories:

- Trapping errors
- Preserving an existing condition
- Preserving existing data

Trapping Errors

A TSR committing an error that triggers an interrupt must handle the interrupt to trap the error. Otherwise, the existing interrupt routine, which belongs to the underlying process, would attempt to service an error the underlying process did not commit.

For example, a TSR that accepts keyboard input should include handlers for Interrupts 23h and 1Bh to trap keyboard break signals. When MS-DOS detects Ctrl+C from the keyboard or input stream, it transfers control to Interrupt 23h (Ctrl+C Handler). Similarly, the BIOS keyboard routine calls Interrupt 1Bh (Ctrl+Break Handler) when it detects a Ctrl+Break key combination. Both routines normally terminate the current process.

A TSR that calls MS-DOS should also trap critical errors through Interrupt 24h (Critical Error Handler). MS-DOS functions call Interrupt 24h when they encounter certain hardware errors. The TSR must not allow the existing interrupt routine to service the error, since the routine might allow the user to abort service and return control to MS-DOS. This would terminate both the
TSR and the underlying process. By handling Interrupt 24h, the TSR retains control if a critical error occurs.

An error-trapping handler differs in two ways from a TSR’s other handlers:

1. It is temporary, in service only while the TSR executes. At startup, the TSR copies the handler’s address to the interrupt vector table; it then restores the original vector before returning.

2. It provides complete service for the interrupt; it does not pass control on to the original routine.

Error-trapping handlers often set a flag to let the TSR know the error has occurred. For example, a handler for Interrupt 1Bh might set a flag when the user presses \texttt{CTRL+BREAK}. The TSR can check the flag as it polls for keyboard input, as shown here:

```assembly
BrkHandler PROC FAR ; Handler for Interrupt 1Bh
.
.
mov cs:BreakFlag, TRUE ; Raise break flag
iret ; Terminate interrupt

BrkHandler ENDP
.
.
mov BreakFlag, FALSE ; Initialize break flag

poll:
.
.
cmp BreakFlag, TRUE ; Keyboard break pressed?
je exit ; If so, break polling loop
mov ah, 1
int 16h ; Key waiting?
jnz poll ; If not, repeat polling loop
```

Preserving an Existing Condition

A TSR and its interrupt handlers must preserve register values so that all registers are returned intact to the interrupted process. This is usually done by pushing the registers onto the stack before changing them, then popping the original values before returning.

Setting up a new stack is another important safeguard against interference. A TSR should usually provide its own stack to avoid the possibility of overrunning the current stack. Exceptions to this rule are simple TSRs such as the sample program ALARM that make minimal stack demands.
A TSR that alters the video configuration should return the configuration to its original state upon return. Video configuration includes cursor position, cursor shape, and video mode. The services provided through Interrupt 10h enable a TSR to determine the existing configuration and alter it if necessary.

However, some applications set video parameters by directly programming the video controller. When this happens, BIOS remains unaware of the new configuration and consequently returns inaccurate information to the TSR. Unfortunately, there is no solution to this problem if the controller’s data registers provide write-only access and thus cannot be queried directly. For more information on video controllers, refer to Richard Wilton, *Programmer’s Guide to the PC & PS/2 Video Systems*. (See “Books for Further Reading” in the Introduction.)

**Preserving Existing Data**

A TSR requires its own disk transfer area (DTA) if it calls MS-DOS functions that access the DTA. These include file control block functions and Functions 11h, 12h, 4Eh, and 4Fh. The TSR must switch to a new DTA to avoid overwriting the one belonging to the interrupted process. On becoming active, the TSR calls Function 2Fh to obtain the address of the current DTA. The TSR stores the address and then calls Function 1Ah to establish a new DTA. Before returning, the TSR again calls Function 1Ah to restore the address of the original DTA.

MS-DOS versions 3.1 and later allow a TSR to preserve extended error information. This prevents the TSR from destroying the original information if it commits an MS-DOS error. The TSR retrieves the current extended error data by calling MS-DOS Function 59h. It then copies registers AX, BX, CX, DX, SI, DI, DS, and ES to an 11-word data structure in the order given. MS-DOS reserves the last three words of the structure, which should each be set to zero. Before returning, the TSR calls Function 5Dh with AL = 0Ah and DS:DX pointing to the data structure. This call restores the extended error data to their original state.

**Communicating Through the Multiplex Interrupt**

The Multiplex interrupt (Interrupt 2Fh) provides the Microsoft-approved way for a program to verify the presence of an installed TSR and to exchange information with it. MS-DOS version 2.x uses Interrupt 2Fh only as an interface for the resident print spooler utility PRINT.COM. Later MS-DOS versions standardize calling conventions so that multiple TSRs can share the interrupt.

A TSR chains to the Multiplex interrupt by setting up a handler. The TSR’s installation code records the Interrupt 2Fh vector and then replaces it with the address of the new multiplex handler.
The Multiplex Handler

A program communicates with a multiplex handler by calling Interrupt 2Fh with an identity number in the AH register. As each handler in the chain gains control, it compares the value in AH with its own identity number. If the handler finds that it is not the intended recipient of the call, it passes control to the previous handler. The process continues until control reaches the target handler. When the target handler finishes its tasks, it returns via an IRET instruction to terminate the interrupt.

The target handler determines its tasks from the function number in AL. Convention reserves Function 0 as a request for installation status. A multiplex handler must respond to Function 0 by setting AL to 0FFh, to inform the caller of the handler’s presence in memory. The handler should also return other information to provide a completely reliable identification. For example, it might return in ES:BX a far pointer to the TSR’s copyright notice. This assures the caller it has located the intended TSR and not another TSR that has already claimed the identity number in AH.

Identity numbers range from 192 to 255, since MS-DOS reserves lesser values for its own use. During installation, a TSR must verify the uniqueness of its number. It must not set up a multiplex handler identified by a number already in use. A TSR usually obtains its identity number through one of the following methods:

- The programmer assigns the number in the program.
- The user chooses the number by entering it as an argument in the command line, placing it into an environment variable, or by altering the contents of an initialization file.
- The TSR selects its own number through a process of trial and error.

The last method offers the most flexibility. It finds an identity number not currently in use among the installed multiplex handlers and does not require intervention from the user.

To use this method, a TSR calls Interrupt 2Fh during installation with AH = 192 and AL = 0. If the call returns AL = 0FFh, the program tests other registers to determine if it has found a prior installation of itself. If the test fails, the program resets AL to zero, increments AH to 193, and again calls Interrupt 2Fh. The process repeats with incrementing values in AH until the TSR locates a prior installation of itself—in which case it should abort with an appropriate message to the user—or until AL returns as zero. The TSR can then use the value in AH as its identity number and proceed with installation.

The SNAP.ASM program in this chapter demonstrates how a TSR can use this trial-and-error method to select a unique identity number. During installation, the program calls Interrupt 2Fh to verify that SNAP is not already installed. When
deinstalling, the program again calls Interrupt 2Fh to locate the resident TSR in memory. SNAP’s multiplex handler services the call and returns the address of the resident code’s program-segment prefix. The calling program can then locate the resident code and deinstall it, as explained in “Deinstalling a TSR,” following.

Using the Multiplex Interrupt Under MS-DOS Version 2.x

A TSR can use the Multiplex interrupt under MS-DOS version 2.x, with certain limitations. Under version 2.x, only MS-DOS’s print spooler PRINT, itself a TSR program, provides an Interrupt 2Fh service. The Interrupt 2Fh vector remains null until PRINT or another TSR is installed that sets up a multiplex handler.

Therefore, a TSR running under version 2.x must first check the existing Interrupt 2Fh vector before installing a multiplex handler. The TSR locates the current Interrupt 2Fh handler through Function 35h (Get Interrupt Vector). If the function returns a null vector, the TSR’s handler will be last in the chain of Interrupt 2Fh handlers. The handler must terminate with an IRET instruction rather than pass control to a nonexistent routine.

PRINT in MS-DOS version 2.x does not pass control to the previous handler. If you intend to run PRINT under version 2.x, the program must be installed before other TSRs that also handle Interrupt 2Fh. This places PRINT’s multiplex handler last in the chain of handlers.

Deinstalling a TSR

A TSR should provide a means for the user to remove or “deinstall” it from memory. Deinstallation returns occupied memory to the system, offering these benefits:

- The freed memory becomes available to subsequent programs that may require additional memory space.
- Deinstallation restores the system to a normal state. Thus, sensitive programs that may be incompatible with TSRs can execute without the presence of installed routines.

A deinstallation program must first locate the TSR in memory, usually by requesting an address from the TSR’s multiplex handler. When it has located the TSR, the deinstallation program should then compare addresses in the vector table with the addresses of the TSR’s handlers. A mismatch indicates that another TSR has chained a handler to the interrupt routine. In this case, the deinstallation program should deny the request to deinstall. If the addresses of
the TSR’s handlers match those in the vector table, deinstallation can safely continue.
You can deinstall the TSR with these three steps:

1. Restore to the vector table the original interrupt vectors replaced by the handler addresses.

2. Read the segment address stored at offset 2Ch of the resident TSR’s program segment prefix (PSP). This address points to the TSR’s “environment block,” a list of environment variables that MS-DOS copies into memory when it loads a program. Place the block’s address in the ES register and call MS-DOS Function 49h (Release Memory Block) to return the block’s memory to the operating system.

3. Place the resident PSP segment address in ES and again call Function 49h. This call releases the block of memory occupied by the TSR’s code and data.

The example program in the next section demonstrates how to locate a resident TSR through its multiplex handler, and deinstall it from memory.

**Example of an Advanced TSR: SNAP**

This section presents SNAP, a memory-resident program that demonstrates most of the techniques discussed in this chapter. SNAP takes a snapshot of the current screen and copies the text to a specified file. SNAP accommodates screens with various column and line counts, such as CGA’s 40-column mode or VGA’s 50-line mode. The program ignores graphics screens.

Once installed, SNAP occupies approximately 7.5K of memory. When it detects the **ALT+LEFT SHIFT+S** key combination, SNAP displays a prompt for a file specification. The user can type a new filename, accept the previous filename by pressing **ENTER**, or cancel the request by pressing **ESC**.

SNAP reads text directly from the video buffer and copies it to the specified file. The program sets the file pointer to the end of the file so that text is appended without overwriting previous data. SNAP copies each line only to the last character, ignoring trailing spaces. The program adds a carriage return–linefeed sequence (0D0Ah) to the end of each line. This makes the file accessible to any text editor that can read ASCII files.

To demonstrate how a program accesses resident data through the Multiplex interrupt, SNAP can reset the display attribute of its prompt box. After installing SNAP, run the main program with the /C option to change box colors:

```
SNAP /Cxx
```

The argument **xx** specifies the desired attribute as a two-digit hexadecimal number—for example, 7C for red on white, or 0F for monochrome high
intensity. For a list of color and monochrome display attributes, refer to the “Tables” section of the Reference.

SNAP can deinstall itself, provided another TSR has not been loaded after it. Deinstall SNAP by executing the main program with the /D option:

SNAP /D

If SNAP successfully deinstalls, it displays the following message:

TSR deinstalled

**Building SNAP.EXE**

SNAP combines four modules: SNAP.ASM, COMMON.ASM, HANDLERS.ASM, and INSTALL.ASM. Source files are located on one of your distribution disks. Each module stores temporary code and data in the segments INSTALLCODE and INSTALLDATA. These segments apply only to SNAP’s installation phase; MS-DOS recovers the memory they occupy when the program exits through the terminate-and-stay-resident function. The following briefly describes each module:

- SNAP.ASM contains the TSR’s main code and data.
- COMMON.ASM contains procedures used by other example programs.
- HANDLERS.ASM contains interrupt handler routines for Interrupts 08, 09, 10h, 13h, 15h, 28h, and 2Fh. It also provides simple error-trapping handlers for Interrupts 1Bh, 23h, and 24h. Additional routines set up and deinstall the handlers.
- INSTALL.ASM contains an exit routine that calls the terminate-and-stay-resident function and a deinstallation routine that removes the program from memory. The module includes error-checking services and a command-line parser.

This building-block approach allows you to create other TSRs by replacing SNAP.ASM and linking with the HANDLERS and INSTALL object modules. The library of routines accommodates both keyboard-activated and time-activated TSRs. A time-activated TSR is a program that activates at a predetermined time of day, similar to the example program ALARM introduced earlier in this chapter. The header comments for the Install procedure in HANDLERS.ASM explain how to install a time-activated TSR.

You can write new TSRs in assembly language or any high-level language that conforms to the Microsoft conventions for ordering segments. Regardless of the language, the new code must not invoke an MS-DOS function that sets up the I/O stack (see “Interrupting MS-DOS Functions,” earlier in this chapter). Code
in Microsoft C, for example, must not call `getche` or `kbhit`, since these functions in turn call MS-DOS Functions 01 and 0Bh.

Code written in a high-level language must not check for stack overflows. Compiler-generated stack probes do not recognize the new stack setup when the TSR executes, and therefore must be disabled. The example program BELL.C, included on disk with the TSR library routines, demonstrates how to disable stack checking in Microsoft C using the `check_stack` pragma.

**Outline of SNAP**

The following sections outline in detail how SNAP works. Each part of the outline covers a specific portion of SNAP’s code. Headings refer to earlier sections of this chapter, providing cross-references to SNAP’s key procedures. For example, the part of the outline that describes how SNAP searches for its startup signal refers to the section “Auditing Hardware Events for TSR Requests,” earlier in this chapter.

Figures 11.2 through 11.4 are flowcharts of the SNAP program. Each chart illustrates a separate phase of SNAP’s operation, from installation through memory-residency to deinstallation.
Figure 11.2  Flowchart for SNAP.EXE: Installation Phase
Figure 11.3  Flowchart for SNAP.EXE: Resident Phase
Refer to the flowcharts as you read the following outline. They will help you maintain perspective while exploring the details of SNAP's operation. Text in the outline cross-references the charts.

Note that information in both the outline and the flowcharts is generic. Except for references to the SNAP procedure, all descriptions in the outline and the
flowcharts apply to any TSR created with the HANDLERS and INSTALL modules.

Auditing Hardware Events for TSR Requests

To search for its startup signal, SNAP audits the keyboard with an interrupt handler for either Interrupt 09 (keyboard) or Interrupt 15h (Miscellaneous System Services). The Install procedure determines which of the two interrupts to handle based on the following code:

```
.IF     HotScan == 0 ; If valid scan code given:
   mov     ah, HotShift  ; AH = hour to activate
   mov     al, HotMask   ; AL = minute to activate
   call    GetTimeToElapse ; Get number of 5-second intervals
   mov     CountDown, ax ; to elapse before activation
.
.ELSE                   ; Force use of KeybrdMonitor as
                     ; keyboard handler
   cmp     Version, 031Eh ; DOS Version 3.3 or higher?
   jb      setup           ; No?  Skip next step
.
   ; Test for IBM PS/2 series. If not PS/2, use Keybrd and
   ; Skip MiscServ as handlers for Interrupts 09 and 15h
   ; respectively. If PS/2 system set up KeybrdMonitor as the
   ; Interrupt 09 handler. Audit keystrokes with MiscServ
   ; handler, which searches for the hot key by handling calls
   ; to Interrupt 15h (Miscellaneous System Services). Refer to
   ; Section 11.2.1 for more information about keyboard handlers.
   mov     ax, 0C00h       ; Function 0Ch (Get System
   int     15h             ;   Configuration Parameters)
   sti                     ; Compaq ROM may leave disabled
   jc      setup           ; If carry set,
   or      ah, ah          ; or if AH not 0,
   jnz     setup           ; services are not supported
.
   ; Test bit 4 to see if Intercept is implemented
   test    BYTE PTR es:[bx+5], 00010000y
   jz      setup
.
   ; If so, set up MiscServ as Interrupt 15h handler
   mov     ax, OFFSET MiscServ
   mov     WORD PTR intMisc.NewHand, ax
.
.ENDIF
.
   ; Set up KeybrdMonitor as Interrupt 09 handler
   mov     ax, OFFSET KeybrdMonitor
   mov     WORD PTR intKeybrd.NewHand, ax
```

The following describes the code’s logic:
If the program is running under MS-DOS version 3.3 or higher and if Interrupt 15h supports Function 4Fh, set up handler MiscServ to search for the hot key. Handle Interrupt 09 with KeybMonitor only to maintain the keyboard active flag.

Otherwise, set up a handler for Interrupt 09 to search for the hot key. Handle calls to Interrupt 15h with the routine SkipMiscServ, which contains this single instruction:

```
j mp cs: int Misc. OldHand
```

The jump immediately passes control to the original Interrupt 15h routine; thus, SkipMiscServ has no effect. It serves only to simplify coding in other parts of the program.

At each keystroke, the keyboard interrupt handler (either Keyb or MiscServ) calls the procedure CheckHotKey with the scan code of the current key. CheckHotKey compares the scan code and shift status with the bytes HotScan and HotShift. If the current key matches, CheckHotKey returns the carry flag clear to indicate that the user has pressed the hot key.

If the keyboard handler finds the carry flag clear, it sets the flag TsrRequestFlag and exits. Otherwise, the handler transfers control to the original interrupt routine to service the interrupt.

The timer handler Clock reads the request flag at every occurrence of the timer interrupt. Clock takes no action if it finds a zero value in TsrRequestFlag. Figures 11.1 and 11.3 depict the relationship between the keyboard and timer handlers.

**Monitoring System Status**

Because SNAP produces output to both video and disk, it avoids interrupting either video or disk operations. The program uses interrupt handlers Video and DiskIO to monitor Interrupts 10h (video) and 13h (disk). SNAP also avoids interrupting keyboard use. The instructions at the far label KeybMonitor serve as the monitor handler for Interrupt 09 (keyboard).

The three handlers perform similar functions. Each sets an active flag and then calls the original routine to service the interrupt. When the service routine returns, the handler clears the active flag to indicate that the device is no longer in use.
The BIOS Interrupt 13h routine clears or sets the carry flag to indicate the operation’s success or failure. `DiskIO` therefore preserves the flags register when returning, as shown here:

```
DiskIO  PROC    FAR
    mov     cs:intDiskIO.Flag, TRUE ; Set active flag
    ; Simulate interrupt by pushing flags and far-calling old
    ; Int 13h routine
    pushf
    call    cs:intDiskIO.OldHand
    ; Clear active flag without disturbing flags register
    mov     cs:intDiskIO.Flag, FALSE
    sti                             ; Enable interrupts
    ; Simulate IRET without popping flags (since services use
    ; carry flag)
    ret     2
DiskIO  ENDP
```

The terminating `RET 2` instruction discards the original flags from the stack when the handler returns.

**Determining Whether to Invoke the TSR**

The procedure `CheckRequest` determines whether the TSR:

- Has been requested.
- Can safely interrupt the system.

Each time it executes, the timer handler `Clock` calls `CheckRequest` to read the flag `TsrRequestFlag`. If `CheckRequest` finds the flag set, it scans other flags maintained by the TSR’s interrupt handlers and by MS-DOS. These flags indicate the current system status. As the flowchart in Figure 11.3 shows, `CheckRequest` calls `CheckDos` (described following) to determine the status of the operating system. `CheckRequest` then calls `CheckHardware` to check hardware status.

`CheckHardware` queries the interrupt controller to determine if any device is currently being serviced. It also reads the active flags maintained by the `KeybrdMonitor`, `Video`, and `DiskIO` handlers. If the controller, keyboard, video, and disk are all inactive, `CheckHardware` clears the carry flag and returns.

`CheckRequest` indicates system status with the carry flag. If the procedure returns the carry flag set, the caller exits without invoking the TSR. A clear carry signals that the caller can safely execute the TSR.
Determining MS-DOS Activity

As Figure 11.2 shows, the procedure \texttt{GetDosFlags} locates the InDos flag during SNAP’s installation phase. \texttt{GetDosFlags} calls Function 34h (Get Address of InDos Flag) and then stores the flag’s address in the far pointer \texttt{InDosAddr}.

When called from the \texttt{CheckRequest} procedure, \texttt{CheckDos} reads InDos to determine whether the operating system is active. Note that \texttt{CheckDos} reads the flag directly from the address in \texttt{InDosAddr}. It does not call Function 34h to locate the flag, since it has not yet established whether MS-DOS is active. This follows from the general rule that interrupt handlers must not call any MS-DOS function.

The next two sections more fully describe the procedure \texttt{CheckDos}.

Interrupting MS-DOS Functions

Figure 11.3 shows that the call to \texttt{CheckDos} can initiate either from \texttt{Clock} (timer handler) or \texttt{Idle} (Interrupt 28h handler). If \texttt{CheckDos} finds the InDos flag set, it reacts in different ways, depending on the caller:

- If called from \texttt{Clock}, \texttt{CheckDos} cannot know which MS-DOS function is active. In this case, it returns the carry flag set, indicating that \texttt{Clock} must deny the request for the TSR.
- If called from \texttt{Idle}, \texttt{CheckDos} assumes that one of the low-order polling functions is active. It therefore clears the carry flag to let the caller know the TSR can safely interrupt the function.

For more information on this topic, see the section “Interrupting MS-DOS Functions,” earlier in this chapter.

Monitoring the Critical Error Flag

The procedure \texttt{GetDosFlags} (Figure 11.2) determines the address of the Critical Error flag. The procedure stores the flag’s address in the far pointer \texttt{CritErrAddr}.

When called from either the \texttt{Clock} or \texttt{Idle} handlers, \texttt{CheckDos} reads the Critical Error flag. A nonzero value in the flag indicates that the Critical Error Handler (Interrupt 24h) is processing a critical error and the TSR must not interrupt. In this case, \texttt{CheckDos} sets the carry flag and returns, causing the caller to exit without executing the TSR.

Trapping Errors

As Figure 11.3 shows, \texttt{Clock} and \texttt{Idle} invoke the TSR by calling the procedure \texttt{Activate}. Before calling the main body of the TSR, \texttt{Activate} sets up the following handlers:
<table>
<thead>
<tr>
<th>Handler Name</th>
<th>For Interrupt</th>
<th>Receives Control When</th>
</tr>
</thead>
<tbody>
<tr>
<td>CtrlBreak</td>
<td>1Bh (CTRL+BREAK Handler)</td>
<td>CTRL+BREAK sequence entered at keyboard</td>
</tr>
<tr>
<td>CtrlC</td>
<td>23h (CTRL+C Handler)</td>
<td>MS-DOS detects a CTRL+C sequence from the keyboard or input stream</td>
</tr>
<tr>
<td>CritError</td>
<td>24h (Critical Error Handler)</td>
<td>MS-DOS encounters a critical error</td>
</tr>
</tbody>
</table>

These handlers trap keyboard break signals and critical errors that would otherwise trigger the original handler routines. The CtrlBreak and CtrlC handlers contain a single IRET instruction, thus rendering a keyboard break ineffective. The CritError handler contains the following instructions:

```asm
CritError PROC FAR
    sti
    sub    al, al          ; Assume DOS 2.x
    mov    al, 0           ; Set AL = 0 for ignore error
    .IF     cs:maj or != 2 ; If DOS 3.x, set AL = 3
        mov    al, 3           ; DOS call fails
    .ENDIF
    iret
CritError ENDP
```

The return code in AL stops MS-DOS from taking further action when it encounters a critical error.

As an added precaution, Activate also calls Function 33h (Get or Set CTRL+BREAK Flag) to determine the current setting of the checking flag. Activate stores the setting, then calls Function 33h again to turn off break checking.

When the TSR’s main procedure finishes its work, it returns to Activate, which restores the original setting for the checking flag. It also replaces the original vectors for Interrupts 1Bh, 23h, and 24h.

SNAP’s error-trapping safeguards enable the TSR to retain control in the event of an error. Pressing CTRL+BREAK or CTRL+C at SNAP’s prompt has no effect. If the user specifies a nonexistent drive—a critical error—SNAP merely beeps the speaker and returns normally.

**Preserving an Existing Condition**

Activate records the stack pointer SS:SP in the doubleword OldStackAddr. The procedure then resets the pointer to the address of a new stack before calling the TSR. Switching stacks ensures that SNAP has adequate stack depth while it executes.

The label NewStack points to the top of the new stack buffer, located in the code segment of the HANDLERS.ASM module. The equate constant
STACK_SI Z determines the size of the stack. The include file TSR.INC contains the declaration for STACK_SI Z.

Activate preserves the values in all registers by pushing them onto the new stack. It does not push DS, since that register is already preserved in the Clock or Idle handler.

SNAP does not alter the application’s video configuration other than by moving the cursor. Figure 11.3 shows that Activate calls the procedure Snap, which executes Interrupt 10h to determine the current cursor position. Snap stores the row and column in the word OldPos. The procedure restores the cursor to its original location before returning to Activate.

Preserving Existing Data
Because SNAP does not call an MS-DOS function that writes to the DTA, it does not need to preserve the DTA belonging to the interrupted process. However, the code for switching and restoring the DTA is included withinIFDEF blocks in the procedure Activate. The equate constant DTA_SI Z, declared in the TSR.INC file, governs the assembly of the blocks as well as the size of the new DTA.

It is possible for SNAP to overwrite existing extended error information by committing a file error. The program does not attempt to preserve the original information by calling Functions 59h and 5Dh. In certain rare instances, this may confuse the interrupted process after SNAP returns.

Communicating Through the Multiplex Interrupt
The program uses the Multiplex interrupt (Interrupt 2Fh) to

- Verify that SNAP is installed.
- Select a unique multiplex identity number.
- Locate resident data.

For more information about Interrupt 2Fh, see the section “Communicating through the Multiplex Interrupt,” earlier in this chapter.

SNAP accesses Interrupt 2Fh through the procedure Call Mul ti pl ex, as shown in Figures 11.2 and 11.4. By searching for a prior installation, Call Mul ti pl ex ensures that SNAP is not installed more than once. During deinstallation, Call Mul ti pl ex locates data required to deinstall the resident TSR.

The procedure Mul ti pl ex serves as SNAP’s multiplex handler. When it recognizes its identity number in AH, Mul ti pl ex determines its tasks from the function number in the AL register. The handler responds to Function 0 by
returning AL equalling 0FFh and ES:DI pointing to an identifier string unique to SNAP.

CallMultiplex searches for the handler by invoking Interrupt 2Fh in a loop, beginning with a trial identity number of 192 in AH. At the start of each iteration of the loop, the procedure sets AL to zero to request presence verification from the multiplex handler. If the handler returns 0FFh in AL, CallMultiplex compares its copy of SNAP’s identifier string with the text at memory location ES:DI. A failed match indicates that the multiplex handler servicing the call is not SNAP’s handler. In this case, CallMultiplex increments AH and cycles back to the beginning of the loop.

The process repeats until the call to Interrupt 2Fh returns a matching identifier string at ES:DI, or until AL returns as zero. A matching string verifies that SNAP is installed, since its multiplex handler has serviced the call. A return value of zero indicates that SNAP is not installed and that no multiplex handler claims the trial identity number in AH. In this case, SNAP assigns the number to its own handler.

Deinstalling a TSR

During deinstallation, CallMultiplex locates SNAP’s multiplex handler as described previously. The handler Multiplex receives the verification request and returns in ES the code segment of the resident program.

Deinstall reads the addresses of the following interrupt handlers from the data structure in the resident code segment:

<table>
<thead>
<tr>
<th>Handler Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clock</td>
<td>Timer handler</td>
</tr>
<tr>
<td>Keybrd</td>
<td>Keyboard handler (non-PS/2)</td>
</tr>
<tr>
<td>KeybrdMonitor</td>
<td>Keyboard monitor handler (PS/2)</td>
</tr>
<tr>
<td>Video</td>
<td>Video monitor handler</td>
</tr>
<tr>
<td>DiskIO</td>
<td>Disk monitor handler</td>
</tr>
<tr>
<td>SkipMiscServ</td>
<td>Miscellaneous Systems Services handler (non-PS/2)</td>
</tr>
<tr>
<td>MiscServ</td>
<td>Miscellaneous Systems Services handler (PS/2)</td>
</tr>
<tr>
<td>Idle</td>
<td>MS-DOS Idle handler</td>
</tr>
<tr>
<td>Multiplex</td>
<td>Multiplex handler</td>
</tr>
</tbody>
</table>

Deinstall calls MS-DOS Function 35h (Get Interrupt Vector) to retrieve the current vectors for each of the listed interrupts. By comparing each handler address with the corresponding vector, Deinstall ensures that SNAP can be safely deinstalled. Failure in any of the comparisons indicates that another TSR has been installed after SNAP and has set up a handler for the same interrupt. In
this case, Deinstall returns an error code, stopping the program with the following message:

Can’t deinstall TSR

If all addresses match, Deinstall calls Interrupt 2Fh with SNAP’s identity number in AH and AL set to 1. The handler Multiplex responds by returning in ES the address of the resident code’s PSP. Deinstall then calls MS-DOS Function 2Fh (Set Interrupt Vector) to restore the vectors for the original service routines. This is called “unhooking” or “unchaining” the interrupt handlers.

After unhooking all of SNAP’s interrupt handlers, Deinstall returns with AX pointing to the resident code’s PSP. The procedure FreeTsr then calls MS-DOS Function 49h (Release Memory) to return SNAP’s memory to the operating system. The program ends with the message

TSR deinstalled

to indicate a successful deinstallation.

Deinstalling SNAP does not guarantee more available memory space for the next program. If another TSR loads after SNAP but handles interrupts other than 08, 09, 10h, 13h, 15h, 28h, or 2Fh, SNAP still deinstalls properly. The result is a harmless gap of deallocated memory formerly occupied by SNAP. MS-DOS can use the free memory to store the next program’s environment block. However, MS-DOS loads the program itself above the still-resident TSR.
Mixed-language programming allows you to combine the unique strengths of Microsoft Basic, C, C++, and FORTRAN with your assembly-language routines. Any one of these languages can call MASM routines, and you can call any of these languages from within your assembly-language programs. This makes virtually all the routines from high-level-language libraries available to a mixed-language program.

MASM 6.1 provides mixed-language features similar to those in high-level languages. For example, you can use the **INVOKE** directive to call high-level-language procedures, and the assembler handles the argument-passing details for you. You can also use H2INC to translate C header files to MASM include files, as explained in Chapter 20 of *Environment and Tools*.

The mixed-language features of MASM 6.1 do not make older methods of defining mixed-language interfaces obsolete. In most cases, mixed-language programs written with earlier versions of MASM will assemble and link correctly under MASM 6.1. (For more information, see Appendix A.)

This chapter explains how to write assembly routines that can be called from high-level-language modules and how to call high-level language routines from MASM. You should already understand the languages you want to combine and should know how to write, compile, and link multiple-module programs with these languages.

This chapter covers only assembly-language interface with C, C++, Basic, and FORTRAN; it does not cover mixed-language programming between high-level languages. The focus here is the Microsoft versions of C, C++, Basic, and FORTRAN, but the same principles apply to other languages and compilers. Many of the techniques used in this chapter are explained in the material in Chapter 7 on writing procedures in assembly language, and in Chapter 8 on multiple-module programming.

The first section of this chapter discusses naming and calling conventions. The next section, “Writing an Assembly Procedure for a Mixed-Language Program,” provides a template for writing an assembly-language procedure that can be
called from another module written in a high-level language. This represents the essence of mixed-language programming. Assembly language is often used for creating fast secondary routines in a large program written in a high-level language.

The third section describes specific conventions for linking assembly-language procedures with modules in C, C++, Basic, and FORTRAN. These language-specific sections also provide details on how the language manages various data structures so that your MASM programs are compatible with the data from the high-level language.

### Naming and Calling Conventions

Each language has its own set of conventions, which fall into two categories:

- The “naming convention” specifies how or if the compiler or assembler alters the name of an identifier before placing it into an object file.
- The “calling convention” determines how a language implements a call to a procedure and how the procedure returns to the caller.

MASM supports several different conventions. The assembler uses C convention when you specify a language type (`langtype`) of C, and Pascal convention for language types `PASCAL`, `BASIC`, or `FORTRAN`. To the assembler, the keywords `BASIC`, `PASCAL`, and `FORTRAN` are synonymous. MASM also supports the `SYSCALL` and `STDCALL` conventions, which mix elements of the C and Pascal conventions.

MASM gives you several ways to set the naming and calling conventions in your assembly-language program. Using `.MODEL` with a `langtype` sets the default for the module. This can also be done with the `OPTION` directive. This is equivalent to the `/Gc` or `/Gd` option from the command line. Procedure prototypes and declarations can specify a `langtype` to override the default.

When you write mixed-language routines, the easiest way to ensure convention compatibility is to adopt the conventions of the called procedure’s language. However, Microsoft languages can change the naming and calling conventions for different procedures. If your program must call a procedure that uses an argument-passing method different from that of the default language, prototype the procedure first with the desired language type. This tells the assembler to override the conventions of the default language and assume the proper conventions for the prototyped procedure. “The MASM/High-Level–Language Interface” section in this chapter explains how to change the default conventions. The following sections provide more detail on the information summarized in Table 12.1.
Table 12.1 Naming and Calling Conventions

<table>
<thead>

</tr>
</tbody>
</table>

* The STDCALL language type uses caller stack cleanup if the :VARARG parameter is used. Otherwise, the called routine must clean up the stack.

Naming Conventions

“Naming convention” refers to the way a compiler or assembler stores the names of identifiers. The first two rows of Table 12.1 show how each language type affects symbol names. SYSCALL leaves symbol names as they appear in the source code, but C and STDCALL add an underscore prefix. PASCAL, BASIC, and FORTRAN change symbols to all uppercase.

The following list describes how these naming conventions affect a variable called Big Time in your source code:

<table>
<thead>
<tr>
<th>Langtype Specified</th>
<th>Characteristics</th>
</tr>
</thead>
<tbody>
<tr>
<td>SYSCALL</td>
<td>Leaves the name unmodified. The linker sees the variable as Big Time.</td>
</tr>
<tr>
<td>C, STDCALL</td>
<td>The assembler (or compiler) adds a leading underscore to the name, but does not change case. The linker sees the variable as _Big Time.</td>
</tr>
<tr>
<td>PASCAL, FORTRAN, BASIC</td>
<td>Converts all names to uppercase. The linker sees the variable as Big Time.</td>
</tr>
</tbody>
</table>

The C Calling Convention

Specify the C language type for assembly-language procedures called from programs that assume the C calling convention. Note that such programs are not necessarily written in C, since other languages can mimic C conventions.
Argument Passing

With the C calling convention, the caller pushes arguments from right to left as they appear in the caller’s argument list. The called procedure returns without removing the arguments from the stack. It is the caller’s responsibility to clean the stack after the call, either by popping the arguments or by adding an appropriate value to the stack pointer SP.

Register Preservation

The called routine must return with the original values in BP, SI, DI, DS, and SS. It must also preserve the direction flag.

Varying Number of Arguments

The additional overhead of cleaning the stack after each call has compensations. It frees the caller from having to pass a set number of arguments to the called procedure each time. Because the first argument in the list is always the last one pushed, it is always on the top of the stack. Thus, it has the same address relative to the frame pointer, regardless of how many arguments were actually passed.

For example, consider the C library function `printf`, which accepts different numbers of arguments. A C program calls the function like this:

```
printf( "Numbers:  %f  %f  %.2f  \n", n1, n2, n3 );
printf( "Also:     %f", n4 );
```

The first line passes four arguments (including the string in quotes) and the second line passes only two arguments. Notice that `printf` has no reliable way of determining how many arguments the caller has pushed. Therefore, the function returns without adjusting the stack. The C calling convention requires the caller to take responsibility for removing the arguments from the stack, since only the caller knows how many arguments it passed.

Use `INVOKE` to call a C-callable function from your assembly-language program, since `INVOKE` automatically generates the necessary stack-cleaning code after the call. You must also prototype the function with the `VARARG` keyword if appropriate, as explained in “Procedures,” Chapter 7. Similarly, when you write a C-callable procedure that accepts a varying number of arguments, include `VARARG` in the procedure’s `PROC` statement.

The Pascal Calling Convention

By default, the `langtype` for `FORTRAN`, `BASIC`, and `PASCAL` selects the Pascal calling convention. This convention pushes arguments left to right so that the last argument is lowest on the stack, and it requires that the called routine remove arguments from the stack.
Argument Passing
Arguments are placed on the stack in the same order in which they appear in the source code. The first argument is highest in memory (because it is also the first argument to be placed on the stack), and the stack grows downward.

Register Preservation
A routine that uses the Pascal calling convention must preserve SI, DI, BP, DS, and SS. For 32-bit code, the EBX, ES, FS, and GS registers must be preserved as well as EBP, ESI, and EDI. The direction flag is also cleared upon entry and must be preserved.

Varying Number of Arguments
Passing a variable number of arguments is not possible with the Pascal calling convention.

The STDCALL and SYSCALL Calling Conventions

A STDCALL procedure adopts the C name and calling conventions when prototyped with the VARARG keyword. Refer to the section “Declaring Parameters with the PROC Directive” in Chapter 7. Without VARARG, the procedure uses the C naming and Pascal calling conventions. STDCALL provides compatibility with 32-bit versions of Microsoft compilers.

As Table 12.1 shows, SYSCALL is identical to the C calling convention, but does not add an underscore prefix to symbols.

Argument Passing
Argument passing order for both STDCALL and SYSCALL is the same as the C calling convention. The caller pushes the arguments from right to left and must remove the parameters from the stack after the call. However, STDCALL requires the called procedure to clean the stack if the procedure does not accept a variable number of arguments.

Register Preservation
Both conventions require the called procedure to preserve the registers BP, SI, DI, DS, and SS. Under STDCALL, the direction flag is clear on entry and must be returned clear.

Varying Number of Arguments
SYSCALL allows a variable number of arguments in the same way as the C calling convention. STDCALL also mimics the C convention when VARARG appears in the called procedure’s declaration or definition. It allows a varying number of arguments and requires the caller to clean the stack. If not declared
or defined with \texttt{VARARG}, the called procedure does not accept a variable argument list and must clean the stack before it returns.

Writing an Assembly Procedure
For a Mixed-Language Program

MASM 6.1 simplifies the coding required for linking MASM routines to high-level-language routines. You can use the \texttt{PROTO} directive to write procedure prototypes, and the \texttt{INVOKE} directive to call external routines. MASM simplifies procedure-related tasks in the following ways:

\begin{itemize}
  \item The \texttt{PROTO} directive improves error checking on argument types.
  \item \texttt{INVOKE} pushes arguments onto the stack and converts argument types to types expected when possible. These arguments can be referenced by their parameter label, rather than as offsets of the stack pointer.
  \item The \texttt{LOCAL} directive following the \texttt{PROC} statement saves places on the stack for local variables. These variables can also be referenced by name, rather than as offsets of the stack pointer.
  \item \texttt{PROC} sets up the appropriate stack frame according to the processor mode.
  \item The \texttt{USES} keyword preserves registers given as arguments.
  \item The C calling conventions specified in the \texttt{PROC} syntax allow for a variable number of arguments to be passed to the procedure.
  \item The \texttt{RET} keyword adjusts the stack upward by the number of bytes in the argument list, removes local variables from the stack, and pops saved registers.
  \item The \texttt{PROC} statement lists parameter names and types. The parameters can be referenced by name inside the procedure.
\end{itemize}

The complete syntax and parameter descriptions for these procedure directives are explained in “Procedures” in Chapter 7. This section provides a template that you can use for writing a MASM routine to be called from a high-level language.

The template looks like this:

\begin{verbatim}
Label PROC [[distance langtype visibility <prologueargs> USES reglist parmlist]]
    LOCAL varlist
    ...
    ...
\end{verbatim}
RET
Label ENDP

Replace the italicized words with appropriate keywords, registers, or variables as defined by the syntax in “Declaring Parameters with the PROC Directive” in Chapter 7.

The distance (NEAR or FAR) and visibility (PUBLIC, PRIVATE, or EXPORT) that you give in the procedure declaration override the current defaults. In some languages, the model can also be specified with command-line options.

The langtype determines the calling convention for accessing arguments and restoring the stack. For information on calling conventions, see “Naming and Calling Conventions” earlier in this chapter.

The types for the parameters listed in the parmlist must be given. Also, if any of the parameters are pointers, the assembler does not generate code to get the value of the pointer references. You must write this code yourself. An example of how to write such code is provided in “Declaring Parameters with the PROC Directive” in Chapter 7.

If you need to code your own stack-frame setup manually, or if you do not want the assembler to generate the standard stack setup and cleanup, see “Passing Arguments on the Stack” and “User-Defined Prologue and Epilogue Code” in Chapter 7.

The MASM/High-Level-Language Interface

Since high-level-language programs require initialization, you must write the main routine of a mixed-language program in the high-level language, or link with the startup code supplied by the high-level-language compiler. This gives the assembly code access to high-level routines or library functions. The next section explains how to link an assembly-language program with C-language startup code.

For procedures with prototypes, INVOKE makes calls from MASM to high-level-language programs, much like procedure or function calls in the high-level language. INVOKE calls procedures and generates the code to push arguments in the order specified by the procedure’s calling convention, and to remove arguments from the stack at the end of the procedure.

INVOKE can also do type checking and data conversion for the argument types so that the procedure receives compatible data. For explanations of how to write procedure prototypes and several examples of procedure declarations and the corresponding prototypes, see “Declaring Procedure Prototypes” in Chapter 7.
For programs that mix assembly language and C, the H2INC utility makes it easy to write prototypes and data declarations for the C procedures you want to call from MASM. H2INC translates the C prototypes and declarations into the corresponding MASM prototypes and declarations, which `INVOKE` can use to call the procedure. The use of H2INC is explained in Chapter 20 in *Environment and Tools*.

Mixed-language programming also allows the main program or a routine to use external data—data defined in the other module. External data is the data that is stored in a set place in memory (unlike dynamic and local data, which is allocated on the stack and heap) and is visible to other modules.

External data is shared by all routines. One of the modules must define the static data, which causes the compiler to allocate storage for the data. The other modules that access the data must declare the data as external.

**Argument Passing**

Each language has its own convention for how an argument is actually passed. If the argument-passing conventions of your routines do not agree, then a called routine receives bad data. Microsoft languages support three different methods for passing an argument:

- **Near reference.** Passes a variable’s near (offset) address, expressed as an offset from the default data segment. This method gives the called routine direct access to the variable itself. Any change the routine makes to the parameter is reflected in the calling routine.

- **Far reference.** Passes a variable’s far (segmented) address. Though slower than passing a near reference, this method is necessary for passing data that lies outside the default data segment. (This is not an issue in Basic unless you have specifically requested far memory.)

- **Value.** Passes only a copy of the variable, not its address. With this method, the called routine gets a copy of the argument on the stack, but has no access to the original variable. The copy is discarded when the routine returns, and the variable retains its original value.

When you pass arguments between routines written in different languages, you must ensure that the caller and the called routine use the same conventions for passing and receiving arguments. In most cases, you should check the argument-passing defaults used by each language and make any necessary adjustments. Most languages have features that allow you to change argument-passing methods.
Register Preservation
A procedure called from any high-level language should preserve the direction flag and the values of BP, SI, DI, SS, and DS. Routines called from MASM must not alter SI, DI, SS, DS, or BP.

Pushing Addresses
Microsoft high-level languages push segment addresses before offsets. This lets the called routine use the LES and LDS instructions to read far addresses from the stack. Furthermore, each word of an argument is placed on the stack in order of significance. Thus, the high word of a long integer is pushed first, followed by the low word.

Array Storage
Most high-level-language compilers store arrays in row-major order. This means that all elements of a row are stored consecutively. The first five elements of an array with four rows and three columns are stored in row-major order as:

\[ A[1, 1], A[1, 2], A[1, 3], A[2, 1], A[2, 2] \]

In column-major order, the column elements are stored consecutively. For example, this same array would be stored in column-major order as:

The C/MASM Interface
This section summarizes the characteristics of the interface between MASM and Microsoft C and QuickC compilers. With the default naming and calling convention, the assembler (or compiler) pushes arguments right to left and adds a leading underscore to routine names.

Compatible Data Types
This list shows the 16-bit C data types and equivalent data types in MASM 6.1. For 32-bit C compilers, int and unsigned int are equivalent to the MASM types SDWORD and DWORD, respectively.

<table>
<thead>
<tr>
<th>C Type</th>
<th>Equivalent MASM Type</th>

<td>int, short</td>
<td>SWORD</td>
</tr>
<tr>
<td>unsigned long</td>
<td>DWORD</td>
</tr>
<tr>
<td>long</td>
<td>SDWORD</td>
</tr>
</tbody>
</table>
float REAL4
double REAL8
long double REAL10

Naming Restrictions
C is case-sensitive and does not convert names to uppercase. Since C normally links with the /NOI command-line option, you should assemble MASM modules with the /Cx or /Cp option to prevent the assembler from converting names to uppercase.
Argument-Passing Defaults

C always passes arrays by reference and all other variables (including structures) by value. C programs in tiny, small, and medium model pass near addresses for arrays, unless another distance is specified. Compact-, large-, and huge-model programs pass far addresses by default. To pass by reference a variable type other than array, use the C-language address-of operator (&).

If you need to pass an array by value, declare the array as a structure member and pass a copy of the entire structure. However, this practice is rarely necessary and usually impractical except for very small arrays, since it can make substantial demands on stack space. If your program must maintain an array through a procedure call, create a temporary copy of the array in heap and provide the copy to the procedure by reference.

Changing the Calling Convention

Put _pascal or _fortran in the C function declaration to specify the Pascal calling convention.

Array Storage

Array declarations give the number of elements. A1[a][b] declares a two-dimensional array in C with a rows and b columns. By default, the array’s lower bound is zero. Arrays are stored by the compiler in row-major order. By default, passing arrays from C passes a pointer to the first element of the array.

String Format

C stores strings as arrays of bytes and uses a null character as the end-of-string delimiter. For example, consider the string declared as follows:

```
char msg[] = "string of text"
```

The string occupies 15 bytes of memory as:

![Figure 12.1 C String Format](image)

Since msg is an array of characters, it is passed by reference.

External Data

In C, the extern keyword tells the compiler that the data or function is external. You can define a static data object in a C module by defining a data object outside all functions and subroutines. Do not use the static keyword in C with a data object that you want to be public.
Structure Alignment
By default, C uses word alignment (unpacked storage) for all data objects longer than 1 byte. This storage method specifies that occasional bytes may be added as padding, so that word and doubleword objects start on an even boundary. In addition, all nested structures and records start on a word boundary. MASM aligns on byte boundaries by default.

When converting .H files with H2INC, you can use the /Zp command-line option to specify structure alignment. If you do not specify the /Zp option, H2INC uses word-alignment. Without H2INC, set the alignment to 2 when declaring the MASM structure, compile the C module with /Zp1, or assemble the MASM module with /Zp2.

Compiling and Linking
Use the same memory model for both C and MASM.

Returning Values
The assembler returns simple data types in registers. Table 12.2 shows the register conventions for returning simple data types to a C program.

<table>
<thead>
<tr>
<th>Data Type</th>
<th>Registers</th>
</tr>
</thead>
<tbody>
<tr>
<td>char</td>
<td>AL</td>
</tr>
<tr>
<td>short, near, int (16-bit)</td>
<td>AX</td>
</tr>
<tr>
<td>short, near, int (32-bit)</td>
<td>EAX</td>
</tr>
<tr>
<td>long, far (16-bit)</td>
<td>High-order portion (or segment address) in DX; low-order portion (or offset address) in AX</td>
</tr>
<tr>
<td>long, far (32-bit)</td>
<td>High-order portion (or segment address) in EDX; low-order portion (or offset address) in EAX</td>
</tr>
</tbody>
</table>

Procedures using the C calling convention and returning type float or type double store their return values into static variables. In multi-threaded programs, this could mean that the return value may be overwritten. You can avoid this by using the Pascal calling convention for multi-threaded programs so float or double values are passed on the stack.

Structures less than 4 bytes long are returned in DX:AX. To return a longer structure from a procedure that uses the C calling convention, you must copy the structure to a global variable and then return a pointer to that variable in the AX register (DX:AX, if you compiled in compact, large, or huge model or if the variable is declared as a far pointer).
Structures, Records, and User-Defined Data Types
You can pass structures, records, and user-defined types as arguments by value or by reference.

Writing Procedure Prototypes
The H2INC utility simplifies the task of writing prototypes for the C functions you want to call from MASM. The C prototype converted by H2INC into a MASM prototype allows **INVOKE** to correctly call the C function. Here are some examples of C functions and the MASM prototypes created with H2INC.

/* Function Prototype Declarations to Convert with H2INC */

```c
long checktypes (  
        char *name,  
        unsigned char a,  
        int b,  
        float d,  
        unsigned int *num);

my_func (float fNum, unsigned int x);

extern my_func1 (char *argv[]);

struct videoconfig _far * _far pascal my_func2 (int, scri);
```

For these C prototypes, H2INC generates this code:

```c
@proto_0        TYPEDEF         PROTO C :PTR SBYTE, :BYTE,  
                 :SWORD, :REAL4, :PTR WORD
checktypes      PROTO           @proto_0

@proto_1        TYPEDEF         PROTO C :REAL4, :WORD
my_func         PROTO           @proto_1

@proto_2        TYPEDEF         PROTO FAR PASCAL :SWORD, :scri
my_func1        PROTO           @proto_2

@proto_3        TYPEDEF         PROTO C :PTR PTR SBYTE
my_func2        PROTO           @proto_3
```
Example
As shown in the following short example, the main module (written in C) calls
an assembly routine, Power2.

```
#include <stdio.h>

extern int Power2( int factor, int power );

void main()
{
    printf( "3 times 2 to the power of 5 is %d\n", Power2( 3, 5 ) );
}
```
Figure 12.2 shows how functions that observe the C calling convention use the stack frame.
The MASM module that contains the Power2 routine looks like this:

```
.MODEL small, c

Power2 PROTO C factor:SWORD, power:SWORD

.CODE

Power2 PROC C factor:SWORD, power:SWORD

  mov     ax, factor    ; Load Arg1 into AX
  mov     cx, power     ; Load Arg2 into CX
  shl     ax, cl        ; AX = AX * (2 to power of CX)

  ret

Power2 ENDP
END
```

The MASM procedure declaration for the Power2 routine specifies the C langtype and the parameters expected by the procedure. The langtype specifies the calling and naming conventions for the interface between MASM and C. The routine is public by default. When the C module calls Power2, it passes two arguments, 3 and 5 by value.

**Using the C Startup Code**

This section explains how to write an assembly-language program that can call C library functions. It links with the C startup module, which performs the necessary initialization required by the library functions.

You must follow these steps when writing such a program:

1. Specify the C convention in the .MODEL statement.
2. Include the following (optional) statement to note linkage with the C startup module:

   ```
   EXTERN _acrtused:abs
   ```

3. Prototype or declare as external all C functions the program references.
4. Include a public procedure called main in your assembly-language module. The C startup code calls _main (which is why all C programs begin with a main function). This procedure serves as the effective entry point for your program.
5. Omit an entry point in the program’s END directive. The C startup code serves as the true entry point when the program runs.
6. Assemble with ML’s /Cx switch to preserve the case of nonlocal names.
The following example serves as a template for these steps. The program calls the C run-time function `printf` to display two variables.

```
.MODEL small, c                        ; Step 1: declare C conventions
EXTERN _acrtused:abs                   ; Step 2: bring in C startup
.printf PROTO NEAR,                   ; Step 3: prototype
pstring:NEAR PTR BYTE, ;         external C
num1:WORD, num2:VARARG ;         routines
.DAT
format BYTE    '%i    %i', 13, 0

.CODE

main    PROC    PUBLIC                  ; Step 4: C startup calls here

INVOKE printf, OFFSET format, ax, bx

END                             ; Step 5: no label on END
```

The C++/MASM Interface

C++ can apply a protocol called a “linkage specification” to mixed-language procedures. This lets you link C++ code in the same way as C code. All information in the preceding section applies when linking assembly-language and C++ routines through the C linkage specification.

The C linkage specification forces the C++ compiler to adopt C conventions—which are not the same as C++ conventions—for listed routines. Since MASM does not specifically support C++ conventions, set the C linkage specification in your C++ code for all mixed-language routines, as shown here:

```
extern "C" declaration
```

where `declaration` is the prototype of an exported C++ function or an imported assembly-language procedure. You can bracket a list of declarations:

```
exern "C"
{
    int WriteLine( short attr, char *string );
    void GoExit( int err );
}
```
or apply the specification to individual prototypes:

extern "C" int WriteLine( short attr, char *string );
extern "C" void GoExit( int err );

Note the syntax remains the same whether `WriteLine` and `GoExit` are exported C++ functions or imported assembly-language routines. The linkage specification applies only to called routines, not to external variables. Use the `extern` keyword (without the “C”) as you normally would when identifying objects external to the C++ module.

The FORTRAN/MASM Interface

This section summarizes the specific details important to calling FORTRAN procedures or receiving arguments from FORTRAN routines that call MASM routines. It includes a sample MASM and FORTRAN module.

A FORTRAN procedure follows the Pascal calling convention by default. This convention passes arguments in the order listed, and the calling procedure removes the arguments from the stack. The naming convention converts all exported names to uppercase.

Compatible Data Types

This list shows the FORTRAN data types that are equivalent to the MASM 6.1 data types.

<table>
<thead>
<tr>
<th>FORTRAN Type</th>
<th>Equivalent MASM Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>CHARACTER*1</td>
<td>BYTE</td>
</tr>
<tr>
<td>INTEGER*1</td>
<td>SBYTE</td>
</tr>
<tr>
<td>INTEGER*2</td>
<td>SWORD</td>
</tr>
<tr>
<td>REAL*4</td>
<td>REAL4</td>
</tr>
<tr>
<td>INTEGER*4</td>
<td>SDWORD</td>
</tr>
<tr>
<td>REAL*8, DOUBLE PRECISION</td>
<td>REAL8</td>
</tr>
</tbody>
</table>

Naming Restrictions

FORTRAN allows 31 characters for identifier names. A digit or an underscore cannot be the first character in an identifier name.

Argument-Passing Defaults

By default, FORTRAN passes arguments by reference as far addresses if the FORTRAN module is compiled in large or huge memory model. It passes them as near addresses if the FORTRAN module is compiled in medium model. Versions of FORTRAN prior to Version 4.0 always require large model.
The FORTRAN compiler passes an argument by value when declared with the `VALUE` attribute. This declaration can occur either in a FORTRAN `INTERFACE` block (which determines how to pass an argument) or in a function or subroutine declaration (which determines how to receive an argument).

In FORTRAN you can apply the `NEAR` (or `FAR`) attribute to reference parameters. These keywords override the default. They have no effect when they specify the same method as the default.

### Changing the Calling Convention

A call to a FORTRAN function or subroutine declared with the `PASCAL` or `C` attribute passes all arguments by value in the parameter list (except for parameters declared with the `REFERENCE` attribute). This change in default passing method applies to function and subroutine definitions as well as to the functions and subroutines described by `INTERFACE` blocks.

### Array Storage

When you declare FORTRAN arrays, you can specify any integer for the lower bound (the default is 1). The FORTRAN compiler stores all arrays in column-major order—that is, the leftmost subscript increments most rapidly. For example, the first seven elements of an array defined as `A[3,4]` are stored as `A[1,1], A[2,1], A[3,1], A[1,2], A[2,2], A[3,2], A[1,3]`.

### String Format

FORTRAN stores strings as a series of bytes at a fixed location in memory, with no delimiter at the end of the string. When passing a variable-length FORTRAN string to another language, you need to devise a method by which the target routine can find the end of the string.

Consider the string declared as

```fortran
CHARACTER*14 MSG
MSG = 'String of text'
```

The string is stored in 14 bytes of memory like this:

![Figure 12.3 FORTRAN String Format](image)

- The string is stored in 14 bytes of memory like this:
Strings are passed by reference. Although FORTRAN has a method for passing length, the variable-length FORTRAN strings cannot be used in a mixed-language interface because other languages cannot access the temporary variable that FORTRAN uses to communicate string length. However, fixed-length strings can be passed if the FORTRAN INTERFACE statement declares the length of the string in advance.

External Data

FORTRAN routines can directly access external data. In FORTRAN you can declare data to be external by adding the EXTERN attribute to the data declaration. You can also access a FORTRAN variable from MASM if it is declared in a COMMON block.

A FORTRAN program can call an external assembly procedure with the use of the INTERFACE statement. However, the INTERFACE statement is not strictly necessary unless you intend to change one of the FORTRAN defaults.

Structure Alignment

By default, FORTRAN uses word alignment (unpacked storage) for all data objects larger than 1 byte. This storage method specifies that occasional bytes may be added as padding, so that word and doubleword objects start on an even boundary. In addition, all nested structures and records start on a word boundary. The MASM default is byte-alignment, so you should specify an alignment of 2 for MASM structures or use the /Zp1 option when compiling in FORTRAN.

Compiling and Linking

Use the same memory model for the MASM and FORTRAN modules.

Returning Values

You must use a special convention to return floating-point values, records, user-defined types, arrays, and values larger than 4 bytes to a FORTRAN module from an assembly procedure. The FORTRAN module creates space in the stack segment to hold the actual return value. When the call to the assembly procedure is made, an extra parameter is passed. This parameter is the last one pushed. The segment address of the return value is contained in SS.

In the assembly procedure, put the data for the return value at the location pointed to by the return value offset. Then copy the return-value offset (located at BP + 6) to AX, and copy SS to DX. This is necessary because the calling module expects DX:AX to point to the return value.
Structures, Records, and User-Defined Data Types

The FORTRAN structure variable, defined with the `STRUCTURE` keyword and declared with the `RECORD` statement, is equivalent to the Pascal `RECORD` and the C `struct`. You can pass structures as arguments by value or by reference (the default).

The FORTRAN types `COMPLEX*8` and `COMPLEX*16` are not directly implemented in MASM. However, you can write structures that are equivalent. The type `COMPLEX*8` has two fields, both of which are 4-byte floating-point numbers; the first contains the real component, and the second contains the imaginary component. The type `COMPLEX` is equivalent to the type `COMPLEX*8`.

The type `COMPLEX*16` is similar to `COMPLEX*8`. The only difference is that each field of the former contains an 8-byte floating-point number.

A FORTRAN `LOGICAL*2` is stored as a 1-byte indicator value (1=true, 0=false) followed by an unused byte. A FORTRAN `LOGICAL*4` is stored as a 1-byte indicator value followed by three unused bytes. The type `LOGICAL` is equivalent to `LOGICAL*4`, unless `$STORAGE:2` is in effect.

To pass or receive a FORTRAN `LOGICAL` type, declare a MASM structure with the appropriate fields.

Varying Number of Arguments

In FORTRAN, you can call routines with a variable number of arguments by including the `VARYING` attribute in your interface to the routine, along with the `C` attribute. You must use the `C` attribute because a variable number of arguments is possible only with the `C` calling convention. The `VARYING` attribute prevents FORTRAN from enforcing a matching number of parameters.

Pointers and Addresses

FORTRAN programs can determine near and far addresses with the `LOCNEAR` and `LOCFAR` functions. Store the result as `INTEGER*2` (with the `LOCNEAR` function) or as `INTEGER*4` (with the `LOCFAR` function). If you pass the result of `LOCNEAR` or `LOCFAR` to another language, be sure to pass by value.
Example
In the following example, the FORTRAN module calls an assembly procedure that calculates $A \times 2^B$, where $A$ and $B$ are the first and second parameters, respectively. This is done by shifting the bits in $A$ to the left $B$ times.

```fortran
INTERFACE TO INTEGER*2 FUNCTION POWER2(A, B)
  INTEGER*2 A, B
END

PROGRAM MAIN
  INTEGER*2 POWER2
  INTEGER*2 A, B
  A = 3
  B = 5
  WRITE (*, *) '3 TIMES 2 TO THE B OR 5 IS ',POWER2(A, B)
END
```

To understand the assembly procedure, consider how the parameters are placed on the stack, as illustrated in Figure 12.4.

![Figure 12.4 FORTRAN Stack Frame](image)

Figure 12.4 assumes that the FORTRAN module is compiled in large model. If you compile the FORTRAN module in medium model, then each argument is passed as a 2-byte, not 4-byte, address. The return address is 4 bytes long because procedures called from FORTRAN must always be FAR.
The assembler code looks like this:

```asm
.MODEL LARGE, FORTRAN

Power2  PROTO FORTRAN, pFactor:FAR PTR SWORD, pPower:FAR PTR SWORD

.CODE

Power2  PROC FORTRAN, pFactor:FAR PTR SWORD, pPower:FAR PTR SWORD

    les     bx, pFactor         ; ES:BX points to factor
    mov     ax, es:[bx]          ; AX = value of factor
    les     bx, pPower           ; ES:BX points to power
    mov     cx, es:[bx]          ; CX = value of power
    shl     ax, cl               ; Multiply by 2^n
    ret                     ; Return result in AX

Power2  ENDP

END
```

The Basic/MASM Interface

This section explains how to call MASM procedures or functions from Basic and how to receive Basic arguments for the MASM procedure. Pascal is the default naming and calling convention, so all lowercase letters are converted to uppercase. Routines defined with the `FUNCTION` keyword return values, but routines defined with `SUB` do not. Basic `DEF FN` functions and `GOSUB` routines cannot be called from another language.

The information provided pertains to Microsoft's Basic and QuickBasic compilers. Differences between the two compilers are noted when necessary.

Compatible Data Types

The following list shows the Basic data types that are equivalent to the MASM 6.1 data types.

<table>
<thead>
<tr>
<th>Basic Type</th>
<th>Equivalent MASM Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>STRING*1</td>
<td>WORD</td>
</tr>
<tr>
<td>INTEGER (X%)</td>
<td>SWORD</td>
</tr>
<tr>
<td>SINGLE (X!)</td>
<td>REAL4</td>
</tr>
<tr>
<td>LONG (X&amp;),</td>
<td>SDWORD</td>
</tr>
<tr>
<td>CURRENCY</td>
<td></td>
</tr>
<tr>
<td>DOUBLE (X#)</td>
<td>REAL8</td>
</tr>
</tbody>
</table>

Naming Conventions

Basic recognizes up to 40 characters of a name. In the object code, Basic also drops any of its reserved characters: %, &, !, #, @, &.
Argument-Passing Defaults

Basic can pass data in several ways and can receive it by value or by near reference. By default, Basic arguments are passed by near reference as 2-byte addresses. To pass a near address, pass only the offset; if you need to pass a far address, pass the segment and offset separately as integer arguments. Pass the segment address first, unless you have specified C compatibility with the CDECL keyword.

Basic passes each argument in a call by far reference when CALLS is used to invoke a routine. You can also use SEG to modify a parameter in a preceding DECLARE statement so that Basic passes that argument by far reference. To pass any other variable type by value, apply the BYVAL keyword to the argument in the DECLARE statement. You cannot pass arrays and user-defined types by value.

```basic
DECLARE SUB Test(BYVAL a%, b%, SEG c%)
CALL Test(x%, y%, z%)
CALLS Test(x%, y%, z%)
```

This CALL statement passes the first argument (a%) by value, the second argument (b%) by near reference, and the third argument (c%) by far reference. The statement

```basic
CALLS Test2(x%, y%, z%)
```

passes each argument by far reference.

Changing the Calling Convention

Including the CDECL keyword in the Basic DECLARE statement enables the C calling and naming conventions. This also allows a call to a MASM procedure with a varying number of arguments.

Array Storage

The DIM statement sets the number of dimensions for a Basic array and also sets the array’s maximum subscript value. In the array declaration `DIM x(a, b)` , the upper bounds (the maximum number of values possible) of the array are a and b. The default lower bound is 0. The default upper bound for an array subscript is 10.

The default for column storage in Basic is column-major order, as in FORTRAN. For an array defined as `DIM Arr%(3,3)` , reference the last element as `Arr%(3,3)` . The first five elements of `Arr(3,3)` are `Arr(0,0), Arr(1,0), Arr(2,0), Arr(0,1), Arr(1,1)`
When you pass an array from Basic to a language that stores arrays in row-major order, use the command-line option /R when compiling the Basic module.

Most Microsoft languages permit you to reference arrays directly. Basic uses an array descriptor, however, which is similar in some respects to a Basic string descriptor. The array descriptor is necessary because Basic handles memory allocation for arrays dynamically, and thus may shift the location of the array in memory.

A reference to an array in Basic is really a near reference to an array descriptor. Array descriptors are always in DGROUP, even though the data may be in far memory. Array descriptors contain information about type, dimensions, and memory locations of data. You can safely pass arrays to MASM routines only if you follow three rules:

- Pass the array’s address by applying the VARPTR function to the first element of the Basic array and passing the result by value. To pass the far address of the array, apply both the VARPTR and VARSEG functions and pass each result by value. The receiving language gets the address of the first element and considers it to be the address of the entire array. It can then access the array with its normal array-indexing syntax.

- The MASM routine that receives the array should not call back to one of the calling program’s routines before it has finished processing the array. Changing data within the caller’s heap—even data unrelated to the array—may change the array’s location in the heap. This would invalidate any further work the called routine performs, since the routine would be operating on the array’s old location.

- Basic can pass any member of an array by value. When passing individual array elements, these restrictions do not apply.

You can apply LBOUND and UBOUND to a Basic array to determine lower and upper bounds, and then pass the results to another routine. This way, the size of the array does not need to be determined in advance.

**String Format**

Basic maintains a 4-byte string descriptor for each string, as shown in the following. The first field of the string descriptor contains a 2-byte integer indicating the length of the actual string text. The second field contains the offset address of this text within the caller’s data segment.

![Basic String Descriptor Format](image-url)
An assembly-language procedure can store a Basic string descriptor as a simple structure, like this:

```assembly
DESC    STRUCT
    len     WORD    ?       ; Length of string
    off     WORD    ?       ; Offset of string
DESC    ENDS

string  BYTE    "This text referenced by a string descriptor"
sdesc   DESC    (LENGTHOF string, string)
```

Version 7.0 or later of the Microsoft Basic Compiler provides new functions that access string descriptors. These functions simplify the process of sharing Basic string data with routines written in other languages.

Earlier versions of Basic offer the **LEN** (Length) and **SADD** (String Address) functions, which together obtain the information stored in a string descriptor. **LEN** returns the length of a string in bytes. **SADD** returns the offset address of a string in the data segment. The caller must provide both pieces of information so the called procedure can locate and read the entire string. The address returned by **SADD** is declared as type **INTEGER** but is actually equivalent to a C near pointer.

If you need to pass the far address of a string, use the **SSEGADD** (String Segment Address) function of Microsoft Basic version 7.0 or later. You can also determine the segment address of the first element with **VARSEG**.

**External Data**
Declaring global data in Basic follows the same two-step process as in other languages:

1. Declare shareable data in Basic with the **COMMON** statement.
2. Identify the shared variables in your assembly-language procedures with the **EXTERN** keyword. Place the **EXTERN** statement outside of a code or data segment when declaring far data.

**Structure Alignment**
Basic packs user-defined types. For MASM structures to be compatible, select byte-alignment.

**Compiling and Linking**
Always use medium model in assembly-language procedures linked with Basic modules. If you are listing other libraries on the LINK command line, specify Basic libraries first. (There are differences between the QBX and command-line compilation. See your Basic documentation.)
Returning Values
Basic follows the usual convention of returning values in AX or DX:AX. If the value is not floating point, an array, or a structured type, or if it is less than 4 bytes long, then the 2-byte integers should be returned from the MASM procedure in AX and 4-byte integers should be returned in DX:AX. For all other types, return the near offset in AX.

User-Defined Data Types
The Basic TYPE statement defines structures composed of individual fields. These types are equivalent to the C struct, FORTRAN record (declared with the STRUCTURE keyword), and Pascal Record types.

You can use any of the Basic data types except variable-length strings or dynamic arrays in a user-defined type. Once defined, Basic types can be passed only by reference.

Varying Number of Arguments
You can vary the number of arguments in Basic when you change the calling convention with CDECL. To call a function with a varying number of arguments, you also need to suppress the type checking that normally forces a call to be made with a fixed number of arguments. In Basic, you can remove this type checking by omitting a parameter list from the DECLARE statement.

Pointers and Addresses
VARSEG returns a variable’s segment address, and VARPTR returns a variable’s offset address. These intrinsic Basic functions enable your program to pass near or far addresses.

Example
This example calls the Power2 procedure in the MASM 6.1 module.

DEFINT A-Z

DECLARE FUNCTION Power2 (A AS INTEGER, B AS INTEGER)

PRINT "3 times 2 to the power of 5 is ";
PRINT Power2(3, 5)

END

The first argument, A, is higher in memory than B because Basic pushes arguments in the same order in which they appear.
Figure 12.6 shows how the arguments are placed on the stack.

![Basic Stack Frame](image)

**Figure 12.6 Basic Stack Frame**

The assembly procedure can be written as follows:

```assembly
.model medium

Power2 PROTO PASCAL, factor:PTR WORD, power:PTR WORD

Power2 PROC PASCAL, factor:PTR WORD, power:PTR WORD

    mov bx, WORD PTR factor ; BX points to factor
    mov ax, [bx]            ; Load factor into AX
    mov bx, WORD PTR power  ; BX points to power
    mov cx, [bx]            ; Load power into CX
    shl ax, cl              ; AX = AX * (2 to power of CX)
    ret

Power2 ENDP

END
```

Note that each parameter must be loaded in a two-step process because the address of each is passed rather than the value. The return address is 4 bytes long because procedures called from Basic must be **FAR**.
CHAPTER 13

Writing 32-Bit Applications

This chapter is an introduction to 32-bit programming for the 80386. The guidelines in this chapter also apply to the 80486 processor, which is basically a faster 80386 with the equivalent of a 80387 floating-point processor. Since you are already familiar with 16-bit real-mode programming, this chapter covers the differences between 16-bit programming and 32-bit protected-mode programming.

The 80386 processor (and its successors such as the 80486) can run in real mode, virtual-86 mode, and in protected mode. In real and virtual-86 modes, the 80386 can run 8086/8088 programs. In protected mode, it can run 80286 programs. The 386 also extends the features of protected mode to include 32-bit operations and segments larger than 64K.

The MS-DOS operating system directly supports 8086/8088 programs, which it runs either in real mode or virtual-86 mode. Native 32-bit 80386 programs can be run by using a “DOS extender,” by using the WINMEM32.DLL facility of Microsoft Windows 3.x, or by running a native 32-bit operating system, such as Microsoft Windows NT. You can use MASM to generate object code (OMF or COFF) for 32-bit programs. To do this, you will need a software development kit such as the Windows SDK for the target environment. Such kits include the linker and other components specific to your chosen operating environment.

32-Bit Memory Addressing

The 80386 has six segment registers. Four of these are familiar to 8086/8088 programmers: CS (Code Segment), SS (Stack Segment), DS (Data Segment), and ES (Extra Segment). The two additional registers, FS and GS, are used as data segment registers.

Memory addresses on 80x86 machines consist of two parts—a segment and an offset. In real-mode programs, the segment is a 16-bit number and the offset is a 16-bit number. Effective addresses are calculated by multiplying the segment by
16 and adding the offset to it. In protected mode, the segment value is not used directly as a number, but instead is an index to a table of “selectors.” Each selector describes a block of memory, including attributes such as the size and location of the block, and the access rights the program has to it (read, write, execute). The effective address is calculated by adding the offset to the base address of the memory block described by the selector.

All segment registers are 16 bits wide. The offset in a 32-bit protected-mode program is itself 32 bits wide, which means that a single segment can address up to 4 gigabytes of memory. Because of this large range, there is little need to use segment registers to extend the range of addresses in 32-bit programs. If all six segment registers are initially set to the same value, then the rest of the program can ignore them and treat the processor as if it used a 32-bit linear address space. This is called 0:32, or flat, addressing. (The full segmented 32-bit addressing mode, in which the segment registers can contain different values, is called 16:32 addressing.) Flat addressing is used by the Windows NT operating system.

Figure 13.1 32-Bit Register Set

**MASM Directives for 32-Bit Programming**

If you use the simplified segment directives, a 32-bit program is surprisingly similar to a program for MS-DOS. Here are the differences:
Supply the `.386` directive, which enables the 32-bit programming features of the 386 and its successors. The `.386` directive must precede the `.MODEL` directive.

For flat-model programming, use the directive

`.MODEL  flat, stdcall`

which tells the assembler to assume flat model (0:32) and to use the Windows NT standard calling convention for subroutine calls.

Precede your data declarations with the `.DATA` directive.

Precede your instruction codes with the `.CODE` directive.

At the end of the source file, place an `END` directive.

**Sample Program**

The following sample is a 32-bit assembly language subroutine, such as might be called from a 32-bit C program written for the Windows NT operating system. The program illustrates the use of a variety of directives to make assembly language easier to read and maintain. Note that with 32-bit flat model programming, there is no longer any need to refer to segment registers, since these are artifacts of segmented addressing.
;* szSearch - An example of 32-bit assembly programming using MASM 6.1
;*
;* Purpose: Search a buffer (rgbSearch) of length cbSearch for the
;*          first occurrence of szTok (null terminated string).
;*
;* Method: A variation of the Boyer-Moore method
;*
;* 1. Determine length of szTok (n)
;* 2. Set array of flags (rgfInTok) to TRUE for each character
;*     in szTok
;* 3. Set current position of search to rgbSearch (pbCur)
;* 4. Compare current position to szTok by searching backwards
;*     from the nth position. When a comparison fails at
;*     position (m), check to see if the current character
;*     in rgbSearch is in szTok by using rgfInTok. If not,
;*     set pbCur to pbCur+(m)+1 and restart compare. If
;*     pbCur reached, increment pbCur and restart compare.
;* 5. Reset rgfInTok to all 0 for next instantiation of the
;*     routine.

.386
.MODEL flat, stdcall

FALSE EQU 0
TRUE EQU NOT FALSE
.DATA
; Flags buffer - data initialized to FALSE. We will
; set the appropriate flags to TRUE during initialization
; of szSearch and reset them to FALSE before exit.
rgfInTok BYTE 256 DUP (FALSE);

.CODE

PBYTE TYPEDEF PTR BYTE

szSearch PROC PUBLIC USES esi edi,
    rgbSearch: PBYTE,
    cbSearch: DWORD,
    szTok: PBYTE

; Initialize flags buffer. This tells us if a character is in
; the search token - Note how we use EAX as an index
; register. This can be done with all extended registers.
    mov     esi, szTok
    xor     eax, eax
.REPEAT
    lodsb
    mov     BYTE PTR rgfInTok[eax], TRUE
.UNTIL (!AL)

; Save count of szTok bytes in EDX
    mov     edx, esi
    sub     edx, szTok
    dec     edx

; ESI will always point to beginning of szTok
    mov     esi, szTok

; EDI will point to current search position
; and will also contain the return value
    mov     edi, rgbSearch

; Store pointer to end of rgbSearch in EBX
    mov     ebx, edi
    add     ebx, cbSearch
    sub     ebx, edx

szSearch ENDP

END
; Initialize ECX with length of szTok
    mov     ecx, edx
.WHILE  ( ecx != 0 )
    dec     ecx             ; Move index to current
    mov     al, [edi+ecx]   ;   characters to compare
    ; If the current byte in the buffer doesn't exist in the
    ; search token, increment buffer pointer to current position
    ; +1 and start over. This can skip up to 'EDX'
    ; bytes and reduce search time.
    .IF     !(rgfInTok[eax])
    add     edi, ecx
    inc     edi             ; Initialize ECX with
    mov     ecx, edx        ; length of szTok
    ; Otherwise, if the characters match, continue on as if
    ; we have a matching token
    .ELSEIF (al == [esi+ecx])
    .CONTINUE
    ; Finally, if we have searched all szTok characters,
    ; and land here, we have a mismatch and we increment
    ; our pointer into rgbSearch by one and start over.
    .ELSEIF (!ecx)
    inc     edi
    mov     ecx, edx
    .ENDIF
    ; Verify that we haven't searched beyond the buffer.
    .IF     (edi > ebx)     ; Error value
    mov     edi, 0          ; Error value
    .BREAK
    .ENDIF
    .ENDW
    ; Restore flags in rgfInTok to 0 (for next time).
    mov     esi, szTok
    xor     eax, eax
    .REPEAT
    lodsb
    mov     BYTE PTR rgfInTok[eax], FALSE
    .UNTIL  !AL
    ; Put return value in eax
    mov     eax, edi
    ret
szSearch ENDP
end
APPENDIX A

Differences Between MASM 6.1 and 5.1

For the many users who come to version 6.1 of the Microsoft Macro Assembler directly from the popular MASM 5.1, this appendix describes the differences between the two versions. Version 6.1 contains significant changes, including:

- An integrated development environment called Programmer’s WorkBench (PWB) from which you can write, edit, debug, and execute code.
- Expanded functionality for structures, unions, and type definitions.
- New directives for generating loops and decision statements, and for declaring and calling procedures.
- Simplified methods for applying public attributes to variables and routines in multiple-module programs.
- Enhancements for writing and using macros.
- Flat-model support for Windows NT and new instructions for the 80486 processor.

The OPTION M510 directive (or the /Zm command-line switch) assures nearly complete compatibility between MASM 6.1 and MASM 5.1. However, to take full advantage of the enhancements in MASM 6.1, you will need to rewrite some code written for MASM 5.1.

The first section of this appendix describes the new or enhanced features in MASM 6.1. The second section, “Compatibility Between MASM 5.1 and 6.1,” explains how to:

- Minimize the number of required changes with the OPTION directive.
- Rewrite your existing assembly code, if necessary, to take advantage of the assembler’s enhancements.
New Features of Version 6.1

This section gives an overview of the new features of MASM 6.1 and provides references to more detailed information elsewhere in the documentation. For full explanations and coding examples, see the documentation listed in the cross-references.

The Assembler, Environment, and Utilities

Most of the executable files provided with MASM 6.1 are new or revised. For a complete list of these files, read the PACKING.TXT file on the distribution disk. The book *Getting Started* also provides information about setting up the environment, assembler, and Help system.

The Assembler

The macro assembler, named ML.EXE, can assemble and link in one step. Its new 32-bit operation gives ML.EXE the ability to handle much larger source files than MASM 5.1. The command-line options are new. For example, the /Fl and /Sc options generate instruction timings in the listing file. Command-line options are case-sensitive and must be separated by spaces.

For backward compatibility with MASM 5.1 makefiles, MASM 6.1 includes the MASM.EXE utility. MASM.EXE translates MASM 5.1 command-line options to the new MASM 6.1 command-line options and calls ML.EXE. See the Reference book for details.

H2INC

H2INC converts C include files to MASM include files. It translates data structures and declarations but does not translate executable code. For more information, see Chapter 20 of *Environment and Tools*.

NMAKE

NMAKE replaces the MAKE utility. NMAKE provides new functions for evaluating target files and more flexibility with macros and command-line options. For more information, see *Environment and Tools*.

Integrated Environment

PWB is an integrated development environment for writing, developing, and debugging programs. For information on PWB and the CodeView debugging application, see *Environment and Tools*.

Online Help

MASM 6.1 incorporates the Microsoft Advisor Help system. Help provides a vast database of online help about all aspects of MASM, including the syntax
and timings for processor and coprocessor instructions, directives, command-line options, and support programs such as LINK and PWB.

For information on how to set up the help system, see Getting Started. You can invoke the help system from within PWB or from the QuickHelp program (QH).

**HELPMAKE**

You can use the HELPMAKE utility to create additional help files from ASCII text files, allowing you to customize the online help system. For more information, see Environment and Tools.

**Other Programs**

MASM 6.1 contains the most recent versions of LINK, LIB, BIND, CodeView, and the mouse driver. The CREF program is not included in MASM 6.1. The Source Browser provides the information that CREF provided under MASM 5.1. For more information on the Source Browser, see Chapter 5 of Environment and Tools or Help.

**Segment Management**

This section lists the changes and additions to memory-model support and directives that relate to memory model.

**Predefined Symbols**

The following predefined symbols (also called predefined equates) provide information about simplified segments:

<table>
<thead>
<tr>
<th>Predefined Symbol</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>@stack</td>
<td>DGROUP for near stacks, STACK for far stacks</td>
</tr>
<tr>
<td>@Interface</td>
<td>Information about language parameters</td>
</tr>
<tr>
<td>@Model</td>
<td>Information about the current memory model</td>
</tr>
<tr>
<td>@Line</td>
<td>The source line in the current file</td>
</tr>
<tr>
<td>@Date</td>
<td>The current date</td>
</tr>
<tr>
<td>@FileCur</td>
<td>The current file</td>
</tr>
<tr>
<td>@Time</td>
<td>The current time</td>
</tr>
<tr>
<td>@Environ</td>
<td>The current environment variables</td>
</tr>
</tbody>
</table>

For more information about predefined symbols, see “Predefined Symbols” in Chapter 1.
Enhancements to the ASSUME Directive
MASM automatically generates ASSUME values for the code segment register (CS). It is no longer necessary to include lines such as

ASSUME CS: MyCodeSegment

in your programs. In addition, the ASSUME directive can include ERROR, FLAT, or register type. MASM 6.1 issues a warning when you specify ASSUME values for CS other than the current segment or group.

For more information, see “Setting the ASSUME Directive for Segment Registers” in Chapter 2 and “Defining Register Types with ASSUME” in Chapter 3.

Relocatable Offsets
For compatibility with applications for Windows, the LROFFSET operator can calculate a relocatable offset, which is resolved by the loader at run time. See Help for details.

Flat Model
MASM 6.1 supports the flat-memory model of Windows NT, which allows segments as large as 4 gigabytes. All other memory models limit segment size to 64K for MS-DOS and Windows. For more information about memory models, see “Defining Basic Attributes with .MODEL” in Chapter 2.

Data Types
MASM 6.1 supports an improved data typing. This section summarizes the improved forms of data declarations in MASM 6.1.

Defining Typed Variables
You can now use the type names as directives to define variables. Initializers are unsigned by default. The following example lines are equivalent:

```
var1    DB      25
var1    BYTE    25
```

Signed Types
You can use the SBYTE, SWORD, and SDWORD directives to declare signed data. For more information about these directives, see “Allocating Memory for Integer Variables” in Chapter 4.
Floating-Point Types
MASM 6.1 provides the REAL4, REAL8, and REAL10 directives for declaring floating-point variables. For information on these type directives, see “Declaring Floating-Point Variables and Constants” in Chapter 6.

Qualified Types
Type definitions can now include distance and language type attributes. Procedures, procedure prototypes, and external declarations let you specify the type as a qualified type. A complete description of qualified types is provided in the section “Data Types” in Chapter 1.

Structures
Changes to structures since MASM 5.1 include:

- Structures can be nested.
- The names of structure fields need not be unique. As a result, you must qualify references to field names.
- Initialization of structure variables can continue over multiple lines provided the last character in the line before the comment field is a comma.
- Curly braces and angle brackets are equivalent.

For example, this code works in MASM 6.1:

```
SCORE           STRUCT
    team1         BYTE    10 DUP (?)
    score1        BYTE    ?
    team2         BYTE    10 DUP (?)
    score2        BYTE    ?
SCORE           ENDS

first   SCORE  {"BEARS", 20,        ; This comment is allowed.
    "CUBS", 10 }
    mov     al, [bx].score.team1 ; Field name must be qualified
                                 ; with structure name.
```

You can use OPTION OLDSTRUCTS or OPTION M510 to enable MASM 5.1 behavior for structures. See “Compatibility between MASM 5.1 and 6.1,” later in this appendix. For more information on structures and unions, see “Structures and Unions” in Chapter 5.

Unions
MASM 6.1 allows the definition of unions with the UNION directive. Unions differ from structures in that all fields within a union occupy the same data space. For more information, see “Structures and Unions” in Chapter 5.
Types Defined with TYPEDEF

The TYPEDEF directive defines a type for use later in the program. It is most useful for defining pointer types. For more information on defining types, see “Data Types” in Chapter 1, and “Defining Pointer Types with TYPEDEF” in Chapter 3.

Names of Identifiers

MASM 6.1 accepts identifier names up to 247 characters long. All characters are significant, whereas under MASM 5.1, names are significant to 31 characters only. For more information on identifiers, see “Identifiers” in Chapter 1.

Multiple-Line Initializers

In MASM 6.1, a comma at the end of a line (except in the comment field) implies that the line continues. For example, the following code is legal in MASM 6.1:

```assembly
longstring      BYTE    "This string",
                "continues over two lines."
bitmasks        BYTE    80h, 40h, 20h, 10h,
                08h, 04h, 02h, 01h
```

For more information, see “Statements” in Chapter 1.

Comments in Extended Lines

MASM 5.1 allows a backslash (\) as the line-continuation character if it is the last nonspace character in the line. MASM 6.1 permits a comment to follow the backslash.

Determining Size and Length of Data Labels

The LENGTHOF operator returns the number of data items allocated for a data label. MASM 6.1 also provides the SIZEOF operator. When applied to a type, SIZEOF returns the size attribute of the type expression. When applied to a data label, SIZEOF returns the number of bytes used by the initializer in the label’s definition. In this case, SIZEOF for a variable equals the number of bytes in the type multiplied by LENGTHOF for the variable.

MAFM 6.1 recognizes the LENGTH and SIZE operators for backward compatibility. For a description of the behavior of SIZE under OPTION M510, see “Length and Size of Labels with OPTION M510,” later in this appendix. For obsolete behavior with the LENGTH operator, see also “LENGTH Operator Applied to Record Types,” page 356.

For information on LENGTHOF and SIZEOF, see the following sections in chapter 5: “Declaring and Referencing Arrays,” “Declaring and Initializing
Appendix A Differences Between MASM 6.1 and 5.1

Strings,” “Declaring Structure and Union Variables,” and “Defining Record Variables.”

**HIGHWORD and LOWWORD Operators**

These operators return the high and low words for a given 32-bit operand. They are similar to the `HIGH` and `LOW` operators of MASM 5.1 except that `HIGHWORD` and `LOWWORD` can take only constants as operands, not relocatables (labels).

**PTR and CodeView**

Under MASM 5.1, applying the `PTR` operator to a data initializer determines the size of the data displayed by CodeView. You can still use `PTR` in this manner in MASM 6.1, but it does not affect CodeView typing. Defining pointers with the `TYPEDEF` directive allows CodeView to generate correct information. See “Defining Pointer Types with TYPEDEF” in Chapter 3.

**Procedures, Loops, and Jumps**

With its significant improvements for procedure and jump handling, MASM 6.1 closely resembles high-level–language implementations of procedure calls. MASM 6.1 generates the code to correctly handle argument passing, check type compatibility between parameters and arguments, and process a variable number of arguments. MASM 6.1 can also automatically recast jump instructions to correct for insufficient jump distance.

**Function Prototypes and Calls**

The `PROTO` directive lets you prototype procedures in the same way as high-level languages. `PROTO` enables type-checking and type conversion of arguments when calling the procedure with `INVOKE`. For more information, see “Declaring Procedure Prototypes” in Chapter 7.

The `INVOKE` directive sets up code to call a procedure and correctly pass arguments according to the prototype. MASM 6.1 also provides the `VARARG` keyword to pass a variable number of arguments to a procedure with `INVOKE`. For more information about `INVOKE` and `VARARG`, see “Calling Procedures with `INVOKE`” and “Declaring Parameters with the PROC Directive” in Chapter 7.

The `ADDR` keyword is new since MASM 5.1. When used with `INVOKE`, it provides the address of a variable, in the same way as the address–of operator (`&`) in C. This lets you conveniently pass an argument by reference rather than value. See “Calling Procedures with `INVOKE`” in Chapter 7.
High-Level Flow-Control Constructions

MASM 6.1 contains several directives that generate code for loops and decisions depending on the status of a conditional statement. The conditions are tested at run time rather than at assembly time.

Directives new since MASM 5.1 include .IF, .ELSE, .ELSEIF, .REPEAT, .UNTIL, .UNTILCXZ, .WHILE, and .ENDW. MASM 6.1 also provides the associated .BREAK and .CONTINUE directives for loops and IF statements. For more information, see “Loops” in Chapter 7 and “Decision Directives” on page 171.

Automatic Optimization for Unconditional Jumps

MASM 6.1 automatically determines the smallest encoding for direct unconditional jumps. See “Unconditional Jumps” in Chapter 7.

Automatic Lengthening for Conditional Jumps

If a conditional jump cannot reach its target destination, MASM automatically recasts the code to use an unconditional jump to the target. See “Jump Extending,” page 169.

User-Defined Stack Frame Setup and Cleanup

The prologue code generated immediately after a PROC statement sets up the stack for parameters and local variables. The epilogue code handles stack cleanup. MASM 6.1 allows user-defined prologues and epilogues, as described in “Generating Prologue and Epilogue Code” in Chapter 7.

Simplifying Multiple-Module Projects

MASM 6.1 simplifies the sharing of code and data among modules and makes the use of include files more efficient.

EXTERNDEF in Include Files

MASM 5.1 requires that you declare public and external all data and routines used in more than one module. With MASM 6.1, a single EXTERNDEF directive accomplishes the same task. EXTERNDEF lets you put global data declarations within an include file, making the data visible to all source files that include the file. For more information, see “Using EXTERNDEF” in Chapter 8.

Search Order for Include Files

MASM 6.1 searches for include files in the directory of the main source file rather than in the current directory. Similarly, it searches for nested include files in the directory of the include file. You can specify additional paths to search with the /I command-line option. For more information on include files, see “Organizing Modules” in Chapter 8.
Enforcing Case Sensitivity
In MASM 5.1, sensitivity to case is influenced only by command-line options such as /MX, not the language type given with the .MODEL directive. In MASM 6.1, the language type takes precedence over the command-line options in specifying case sensitivity.
Alternate Names for Externals
The syntax for `EXTERN` allows you to specify an alternate symbol name, which the linker can use to resolve an external reference to an unused symbol. This prevents linkage with unneeded library code, as explained in “Using EXTERN with Library Routines,” Chapter 8.

Expanded State Control
Several directives in MASM 6.1 enable or disable various aspects of the assembler control. These include 80486 coprocessor instructions and use of compatibility options.

The OPTION Directive
The new `OPTION` directive allows you to selectively define the assembler’s behavior, including its compatibility with MASM 5.1. See “Using the OPTION Directive” in Chapter 1 and “Compatibility between MASM 5.1 and 6.1,” later in this appendix.

The .NO87 Directive
The `.NO87` directive disables all coprocessor instructions. For more information, see Help.

The .486 and .486P Directives
MASM 6.1 can assemble instructions specific to the 80486, enabled with the `.486` directive. The `.486P` directive enables 80486 instructions at the highest privilege level (recommended for systems-level programs only). For more information, see Help.

The PUSHCONTEXT and POPCONTEXT Directives
The directive `PUSHCONTEXT` saves the assembly environment, and `POPCONTEXT` restores it. The environment includes the segment register assumes, the radix, the listing and CREF flags, and the current processor and coprocessor. Note that `.NOCREF` (the MASM 6.1 equivalent to `.XCREF`) still determines whether information for a given symbol will be added to Browser information and to the symbol table in the listing file. For more information on listing files, see Appendix C or Help.
New Processor Instructions

MASM 6.1 supports these instructions for the 80486 processor:

<table>
<thead>
<tr>
<th>80486 Instruction</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>BSWAP</td>
<td>Byte swap</td>
</tr>
<tr>
<td>CMPXCHG</td>
<td>Compare and exchange</td>
</tr>
<tr>
<td>INVD</td>
<td>Invalidate data cache</td>
</tr>
<tr>
<td>INVLPG</td>
<td>Invalidate Translation Lookaside Buffer entry</td>
</tr>
<tr>
<td>WBINVD</td>
<td>Write back and invalidate data cache</td>
</tr>
<tr>
<td>XADD</td>
<td>Exchange and add</td>
</tr>
</tbody>
</table>

For full descriptions of these instructions, see the Reference or Help.

Renamed Directives

Although MASM 6.1 still supports the old names in MASM 5.1, the following directives have been renamed for language consistency:

<table>
<thead>
<tr>
<th>MASM 6.1</th>
<th>MASM 5.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>.DOSSEG</td>
<td>DOSSEG</td>
</tr>
<tr>
<td>.LISTIF</td>
<td>.LFCOND</td>
</tr>
<tr>
<td>.LISTMACRO</td>
<td>.XALL</td>
</tr>
<tr>
<td>.LISTMACROALL</td>
<td>.LALL</td>
</tr>
<tr>
<td>.NOCREF</td>
<td>.XCREF</td>
</tr>
<tr>
<td>.NOLIST</td>
<td>.XLIST</td>
</tr>
<tr>
<td>.NOLISTIF</td>
<td>.SFCOND</td>
</tr>
<tr>
<td>.NOLISTMACRO</td>
<td>.SALL</td>
</tr>
<tr>
<td>ECHO</td>
<td>%OUT</td>
</tr>
<tr>
<td>EXTERN</td>
<td>EXTRN</td>
</tr>
<tr>
<td>FOR</td>
<td>IRP</td>
</tr>
<tr>
<td>FORC</td>
<td>IRPC</td>
</tr>
<tr>
<td>REPEAT</td>
<td>REPT</td>
</tr>
<tr>
<td>STRUCT</td>
<td>STRUC</td>
</tr>
<tr>
<td>SUBTITLE</td>
<td>SUBTTL</td>
</tr>
</tbody>
</table>

Specifying 16-Bit and 32-Bit Instructions

MASM 6.1 supports all instructions that work with the extended 32-bit registers of the 80386/486. For certain instructions, you can override the default operand
size with the \texttt{W} (word) and the \texttt{D} (doubleword) suffixes. For details, see the \textit{Reference} or Help.

**Macro Enhancements**

There are significant enhancements to macro functions in MASM 6.1. Directives provide for a variable number of arguments, loop constructions, definitions of text equates, and macro functions.

**Variable Arguments**

MASM 5.1 ignores extra arguments passed to macros. In MASM 6.1, you can pass a variable number of arguments to a macro by appending the \texttt{VARARG} keyword to the last macro parameter in the macro definition. The macro can then reference additional arguments relative to the last declared parameter. This procedure is explained in “Returning Values with Macro Functions” in Chapter 9.

**Required and Default Macro Arguments**

With MASM 6.1, you can use \texttt{REQ} or the := operator to specify required or default arguments. See “Specifying Required and Default Parameters” in Chapter 9.

**New Directives for Macro Loops**

Within a macro definition, \texttt{WHILE} repeats assembly as long as a condition remains true. Other macro loop directives, \texttt{IRP}, \texttt{IRPC}, and \texttt{REPT}, have been renamed \texttt{FOR}, \texttt{FORC}, and \texttt{REPEAT}. For more information, see “Defining Repeat Blocks with Loop Directives” in Chapter 9.

**Text Macros**

The \texttt{EQU} directive retains its old functionality, but MASM 6.1 also incorporates a \texttt{TEXTEQU} directive for defining text macros. \texttt{TEXTEQU} allows greater flexibility than \texttt{EQU}. For example, \texttt{TEXTEQU} can assign to a label the value calculated by a macro function. For more information, see “Text Macros” in Chapter 9.

**The GOTO Directive for Macros**

Within a macro definition, \texttt{GOTO} transfers assembly to a line labeled with a leading colon(:). For more information on \texttt{GOTO}, see Help.

**Macro Functions**

At assembly time, macro functions can determine and return a text value using \texttt{EXITM}. Predefined macro string functions concatenate strings, return the size of a string, and return the position of a substring within a string. For information
on writing your own macro functions, see “Returning Values with Macro Functions” in Chapter 9.

**Predefined Macro Functions**

MASM 6.1 provides the following predefined text macro functions:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Value Returned</th>
</tr>
</thead>
<tbody>
<tr>
<td>@CatStr</td>
<td>A concatenated string</td>
</tr>
<tr>
<td>@InStr</td>
<td>The position of one string within another</td>
</tr>
<tr>
<td>@SizeStr</td>
<td>The size of a string</td>
</tr>
<tr>
<td>@SubStr</td>
<td>A substring</td>
</tr>
</tbody>
</table>

For more information on predefined macros, see “String Directives and Predefined Functions” in Chapter 9.

**MASM 6.1 Programming Practices**

MASM 6.1 provides many features that make it easier for you to write assembly code. If you are familiar with MASM 5.1 programming, you may find it helpful to adopt the following list of new programming practices for programming with MASM 6.1. The list summarizes many of the changes covered in the following section, “Compatibility Between MASM 5.1 and 6.1.”

- Select identifier names that do not begin with the dot operator (\`).
- Use the dot operator (\`) only to reference structure fields, and the plus operator (+) when not referencing structures.
- Different structures can have the same field names. However, the assembler does not allow ambiguous references. You must include the structure type when referring to field names common to two or more structures.
- Separate macro arguments with commas, not spaces.
- Avoid adding extra ampersands in macros. For a list of the new rules about using ampersands in macros, see “Substitution Operator” in Chapter 9 and “OPTION OLDMACROS,” page 372.
- By default, code labels defined with a colon are local. Place two colons after code labels if you want to reference the label outside the procedure.

**Compatibility Between MASM 5.1 and 6.1**

MASM 6.1 provides a “compatibility mode,” making it easy for you to transfer existing MASM 5.1 code to the new version. You invoke the compatibility mode through the `OPTION M510` directive or the `/Zm` command-line switch. This
section explains the changes you may need to make to get your MASM 5.1 code to run under MASM 6.1 in compatibility mode.

Rewriting Code for Compatibility

In some cases, MASM 6.1 with **OPTION M510** does not support MASM 5.1 behavior. In several cases, this is because bugs in MASM 5.1 were corrected. To update your code to MASM 6.1, use the instructions in this section. This usually requires only minor changes.

Many of the topics listed here will not apply to your code. This section discusses topics in order of likelihood, beginning with the most common. In addition, you may have conflicts between identifier names and new reserved words. **OPTION NOKEYWORD** resolves errors generated from the use of reserved words as identifiers. See “OPTION NOKEYWORD,” page 376, for more information.

Bug Fixes Since MASM 5.1

This section lists the differences between MASM 5.1 and MASM 6.1 due to bug corrections since MASM 5.1.

Invalid Use of LOCK, REPNE, and REPNZ

Except in compatibility mode, MASM 6.1 flags illegal uses of the instruction prefixes **LOCK, REPNE, and REPNZ**. The error generated for invalid uses of the **LOCK, REPNE, and REPNZ** prefixes is error A2068:

```
i nstruction prefix not allowed
```

Table A.1 summarizes the correct use of the instruction prefixes. It lists each string instruction with the type of repeat prefix it uses, and indicates whether the instruction works on a source, a destination, or both.

<table>
<thead>
<tr>
<th>Instruction</th>
<th>Repeat Prefix</th>
<th>Source/Destination</th>
<th>Register Pair</th>
</tr>
</thead>
<tbody>
<tr>
<td>MOVSB</td>
<td>REP</td>
<td>Both</td>
<td>DS:SI, ES:DI</td>
</tr>
<tr>
<td>SCAS</td>
<td>REPE/REPNE</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>CMPS</td>
<td>REPE/REPNE</td>
<td>Both</td>
<td>DS:SI, ES:DI</td>
</tr>
<tr>
<td>LODS</td>
<td>--</td>
<td>Source</td>
<td>DS:SI</td>
</tr>
<tr>
<td>STOS</td>
<td>REP</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>INS</td>
<td>REP</td>
<td>Destination</td>
<td>ES:DI</td>
</tr>
<tr>
<td>OUTS</td>
<td>REP</td>
<td>Source</td>
<td>DS:SI</td>
</tr>
</tbody>
</table>
No Closing Quotation Marks in Macro Arguments

In MASM 5.1, you can use both single and double quotation marks (‘ and ”) to begin strings in macro arguments. The assembler does not generate an error or warning if the string does not end with quotation marks on a macro call. Instead, MASM 5.1 considers the remainder of the line to be part of the macro argument containing the opening quote, as if there were a closing quotation mark at the end of the line.

By default, MASM 6.1 now generates error A2046:

`missing single or double quotation mark in string`

so all single and double quotation marks in macro arguments must be matched.

To correct such errors in MASM 6.1, either end the string with a closing quotation mark as shown in the following example, or use the macro escape character (!) to treat the quotation mark literally.

```
; MASM 5.1 code
MyMacro     "all this in one argument"

; Default MASM 6.1 code
MyMacro     "all this in one argument"
```

Making a Scoped Label Public

MASM 5.1 considers code labels defined with a single colon inside a procedure to be local to that procedure if the module contains a .MODEL directive with a language type. Although the label is local, MASM 5.1 does not generate an error if it is also declared PUBLIC. MASM 6.1 generates error A2203:

`cannot declare scoped code label as PUBLIC`

If you want to make a label PUBLIC, it must not be local. You can use the double colon operator to define a non-scoped label, as shown in this example:

```
PUBLIC  publicLabel
publicLabel::                   ; Non-scoped label MASM 6.1
```

Byte Form of BT, BTS, BTC, and BTR Instructions

MASM 5.1 allows a byte argument for the 80386 bit-test instructions, but encodes it as a word argument. The byte form is not supported by the processor.

MASM 6.1 does not support this behavior and generates error A2024:

`invalid operand size for instruction`

Rewrite your code to use a word-sized argument.
Default Values for Record Fields

In MASM 5.1, default values for record fields can range down to $-2^n$, where $n$ is the number of bits in the field. This results in the loss of the sign bit.

MASM 6.1 allows a range of $-2^{n-1}$ to $2^{n-1}$ for default values. Illegal initializers generate error A2071:

initializer too large for specified size

Design Change Issues

MASM 6.1 includes design changes that make the language more consistent. These changes are not affected by the `OPTION` directive, discussed later in this appendix. Therefore, the changes require revisions in your code. In most cases, the necessary revisions are minor and the circumstances requiring changes are rare.

Operands of Different Size

MASM 5.1 does not require operands to agree in size, as the following code illustrates:

```plaintext
.DA?R
var1    DB      ?
var2    DB      ?
.CODE

mov     var1, ax        ; Copy AX to word at var1
```

The operands for the `MOV` instruction do not match in size, yet the instruction assembles correctly. It places the contents of AL into `var1` and AH into `var2`, moving a word of data in one step. If the code defined `var1` as a word value, the instruction

```plaintext
mov     var1, al
```

would also assemble correctly, copying AL into the low byte of `var1` while leaving the high byte unaffected. Except at warning level 0, MASM 5.1 issues a warning to inform you of the size mismatch, but both scenarios are legal.

MASM 6.1 does not accept instructions with operands that do not agree in size. You must specifically “coerce” the size of the memory operand, like this:
Conflicting Structure Declarations
MASM 5.1 allows you to declare two or more structures with the same name. Each declaration replaces the previous declaration. However, the field names from previous declarations still remain in the assembler's list of declared values.

MASM 6.1 does not allow conflicting declarations of a structure. It generates errors A2160 through A2165 for each conflicting declaration. The errors note a specific conflict, such as conflicting number of fields, conflicting names of fields, or conflicting initializers.

Forward References to Text Macros Outside of Expressions
MASM 5.1 allows forward references to text macros in specialized cases. MASM 6.1 with OPTION M510 also permits forward references, but only when the text macro is referenced in an expression. To revise your code, place all macro definitions at the beginning of the file.

HIGH and LOW Applied to Relocatable Operands
In some cases, MASM 5.1 accepts HIGH and LOW applied to relocatable memory expressions. For example, MASM 5.1 allows this code sequence:

```assembly
; MASM 5.1 code
EXTRN var1:WORD
var2 DW 0
mov al, LOW var1 ; These two instructions yield the
mov ah, HIGH var1 ; same as mov ax, OFFSET var1
```

However, the instruction

```assembly
mov ax, LOW var2
```

is not legal. MASM 6.1 generates error A2105:

**HIGH and LOW require immediate operands**

The OFFSET operator is required on these operands in MASM 6.1, as shown in the following. Rewrite your code if necessary.

```assembly
; MASM 6.1 code
mov al, LOW OFFSET var1
mov ah, HI GH OFFSET var2
```

OFFSET Applied to Group Names and Indirect Memory Operands
In MASM 6.1, you cannot apply OFFSET to a group name, indirect argument, or procedure argument. Doing so generates error A2098:
invalid operand for OFFSET

LENGTH Operator Applied to Record Types
In MASM 5.1, the LENGTH operator, when applied to a record type, returns the total number of bits in a record definition.
In MASM 6.1, the statement `LENGTH recordName` returns error A2143:
expected data label

Rewrite your code if necessary. The new `SIZEOF` operator returns information about records in MASM 6.1. For more information, see “Defining Record Variables” in Chapter 5.

Signed Comparison of Hexadecimal Values Using GT, GE, LE, or LT
The rules for two’s-complement comparisons have changed. In MASM 5.1, the expression

```
0FFFFh GT -1
```

is false because the two’s-complement values are equal. However, because hexadecimal numbers are now treated as unsigned, the expression is true in MASM 6.1. To update, rewrite the affected code.

RET Used with a Constant in Procedures with Epilogues
By default in MASM 6.1, the `RET` instruction followed by a constant suppresses automatic generation of epilogue code. MASM 5.1 ignores the operand and generates the epilogue. Remove the argument if necessary. See “Generating Prologue and Epilogue Code” in Chapter 7.

Code Labels at Top of Procedures with Prologues
By default in MASM 5.1, a code label defined on the same line as the first procedure instruction refers to the first byte of the prologue.

In MASM 6.1, a code label defined at the beginning of a procedure refers to the first byte of the procedure after the prologue. If you need to label the start of the prologue code, place the label before the `PROC` statement. For more information, see “Generating Prologue and Epilogue Code” in Chapter 7.

Use of % as an Identifier Character
MAVM 5.1 allows `%` as an identifier character. This behavior leads to ambiguities when `%` is used as the expansion operator in macros. Since `%` is not allowed as a character in MASM 6.1 identifiers, you must change the names of any identifiers containing the `%` character. For a list of legal identifier characters, see “Identifiers” in Chapter 1.

ASSUME CS Set to Wrong Value
With MASM 6.1 you do not need to use the `ASSUME` statement for the CS register. Instead, MASM 6.1 generates an automatic `ASSUME` statement for the code segment register to the current segment or group, as explained in “Setting the ASSUME Directive for Segment Registers” in Chapter 2.
Additionally, MASM 6.1 does not allow explicit ASSUME statements for CS that contradict the automatically set ASSUME statement.

MASM 5.1 allows CS to be assumed to the current segment, even if that segment is a member of a group. With MASM 6.1, this results in warning A4004:

cannot  ASSUME  CS

To avoid this warning with MASM 6.1, delete the ASSUME statement for CS.

**Code Requiring Two-Pass Assembly**

Unlike version 5.1, MASM 6.1 does most of its work on its first pass, then performs as many subsequent passes as necessary. In contrast, MASM 5.1 always assembles in two source passes. As a result, you may need to revise or delete some pass-dependent constructs under MASM 6.1.

**Two-Pass Directives**

To assure compatibility, MASM 6.1 supports 5.1 directives referring to two passes. These include .ERR1, .ERR2, IF1, IF2, ELSEIF1, and ELSEIF2. For second-pass constructs, you must specify OPTION SETIF2, as discussed in “OPTION SETIF2,” page 377. Without OPTION SETIF2, the IF2 and .ERR2 directives cause error A2061:

```
[[ ELSE]] IF2/.ERR2  not  allowed : single-pass assembler
```

MASM 6.1 handles first-pass constructs differently. It treats the .ERR1 directive as .ERR, and the IF1 directive as IF.

The following examples show you how you can rewrite typical pass-sensitive code for MASM 6.1:

- Declare var external only if not defined in current module:

  ; MASM 5.1:
  IF2
  I FNDEF  var
  EXTRN  var:far
  ENDI F
  ENDF
  ; MASM 6.1:
  EXTERNDEF  var:far
Include a file of definitions only once to speed assembly:

; MASM 5.1:
    IF1
        INCLUDE file1.inc
    ENDI F

; MASM 6.1:
    INCLUDE FILE1.INC

Generate a %OUT or .ERR message only once:

; MASM 5.1:
    IF2
        %OUT This is my message
    ENDI F
    IF2
        .ERRNZ A NE B
    ENDI F

; MASM 6.1:
    ECHO This is my message
    .ERRNZ A NE B <ASSERTION FAILURE: A NE B>

Generate an error if a symbol is not defined but may be forward referenced:

; MASM 5.1:
    IF2
        .ERRNDEF var
    ENDI F

; MASM 6.1:
    .ERRNDEF var

For information on conditional directives, see “Conditional Directives,” Chapter 1.

**IFDEF and IFNDEF with Forward-Referenced Identifiers**

If you use a symbol name that has not yet been defined in an **IFDEF** or **IFNDEF** expression, MASM 6.1 returns FALSE for the **IFDEF** expression and TRUE for the **IFNDEF** expression. When **OPTION M510** is enabled, the assembler generates warning A6005:

expression condition may be pass-dependent

To resolve the warning, place the symbol definition before the conditional test.
Address Spans as Constants

The value of offsets calculated on the first assembly pass may not be the same as those calculated on later passes. Therefore, you should avoid comparisons with an address span, as in the following examples:

```
IF (OFFSET var1 - OFFSET var2) EQ 10
WHILE dx LT (OFFSET var1 - OFFSET var2)
REPEAT OFFSET var1 - OFFSET var2
```

However, the DUP operator allows such an expression as its count value. The assembler evaluates the DUP count on every pass, so even expressions involving forward references assemble correctly.

You can also use expressions containing span distances with the .ERR directives, since the assembler evaluates these directives after calculating all offsets:

```
.ERRE OFFSET var1 - OFFSET var2 - 10, <span incorrect>
```

.TYPE with Forward References

MASM 5.1 evaluates .TYPE on both assembly passes. This means it yields zero on the first pass and nonzero on the second pass, if applied to an expression that forward-references a symbol.

MASM 6.1 evaluates .TYPE only on the first assembly pass. As a result, if the operand references a symbol that has not yet been defined, .TYPE yields a value of zero. This means that .TYPE, if used in a conditional-assembly construction, may yield different results in MASM 6.1 than in MASM 5.1.

Obsolete Features No Longer Supported

The following two features are no longer supported by MASM 6.1. Because both are obscure features provided by early versions of the assembler, they probably do not affect your MASM 5.1 code.

The ESC Instruction

MASM 6.1 no longer supports the ESC instruction, which was used to send hand-coded commands to the coprocessor. Because MASM 6.1 recognizes and assembles the full set of coprocessor mnemonics, the ESC instruction is not necessary. Using the ESC instruction generates error A2205:

```
ESC instruction is obsolete: ignored
```

To update MASM 5.1 code, use the coprocessor instructions instead of ESC.
The MSFLOAT Binary Format

MASM 6.1 does not support the .MSFLOAT directive, which provided the Microsoft Binary Format (MSB) for floating-point numbers in variable initializers. Using the .MSFLOAT directive generates error A2204:

. MSFLOAT directive is obsolete: ignored

Use IEEE format or, if MSB format is necessary, initialize variables with hexadecimal values. See “Storing Numbers in Floating-Point Format” in Chapter 6.

Using the OPTION Directive

The OPTION directive lets you control compatibility with MASM 5.1 code. This section explains the differences in MASM 5.1 and MASM 6.1 behavior that the OPTION directive can influence.

The OPTION M510 directive (or /Zm command-line option) initiates all aspects of 5.1 compatibility mode. You can select from among specific characteristics of MASM 5.1 behavior with the OPTION arguments discussed in following sections. Each section also explains how to revise your code if you want to remove OPTION directives from your MASM 5.1 code.

Note If your code includes both .MODEL and OPTION M510, the OPTION M510 statement must appear first. Wherever this appendix suggests using OPTION M510 in your code, you can set the /Zm command-line option instead.

OPTION M510

This section discusses the M510 argument to the OPTION directive, which selects the MASM 5.1 compatibility mode. In this mode, MASM 6.1 implements MASM 5.1 behavior relating to macros, offsets, scope of code labels, structures, identifier names, identifier case, and other behaviors.

The OPTION M510 directive automatically sets the following:

- OPT1 OLDSTRUCTS ; MASM 5.1 structures
- OPT1 OLMACROS ; MASM 5.1 macros
- OPT1 DOTNAME ; Identifiers may begin with a dot (.)
- OPT1 SETIF2: TRUE ; Two-pass code activates on every pass

If you do not have a .386, 386P .486, or 486P directive in your module, then OPTION M510 adds:
OPTION EXPR16 ; 16-bit expression precision
; See "OPTION EXPR16," following
If you do not have a .MODEL directive in your module, OPTION M510 adds:

```
OPTION OFFSET: SEGMENT ; OFFSET operator defaults to
  ; segment-relative
  ; See "OPTION OFFSET," following
```

If you do not have a .MODEL directive with a language specifier in your module, OPTION M510 also adds:

```
OPTION NOSCOPED ; Code labels are not local inside
  ; procedures
  ; See "OPTION NOSCOPED," following

OPTION PROC: PRIVATE ; Labels defined with PROC are not
  ; public by default
  ; See "OPTION PROC," following
```

If you want to remove OPTION M510 from your code (or /Zm from the command line), add the OPTION directive arguments to your module according to the conditions stated earlier.

There may be compatibility issues affecting your code that are supported under OPTION M510, but are not covered by the other OPTION directive arguments. Once you have modified your source code so it no longer requires behavior supported by OPTION M510, you can replace OPTION M510 with other OPTION directive arguments. These compatibility issues are discussed in following sections.

Once you have replaced OPTION M510 with other forms of the OPTION directive and your code works correctly, try removing the OPTION directives, one at a time. Make appropriate source modifications as necessary, until your code uses only MASM 6.1 defaults.

Reserved Keywords Dependent on CPU Mode with OPTION M510

With OPTION M510, keywords and instructions not available in the current CPU mode (such as ENTER under .8086) are not treated as keywords. This also means the USE32, FLAT, FAR32, and NEAR32 segment types and the 80386/486 registers are not keywords with a processor selection less than .386.

If you remove OPTION M510, any reserved word used as an identifier generates a syntax error. You can either rename the identifiers or use OPTION NOKEYWORD. For more information on OPTION NOKEYWORD, see “OPTION NOKEYWORD,” later in this appendix.

Invalid Use of Instruction Prefixes with OPTION M510

Code without OPTION M510 generates errors for all invalid uses of the instruction prefixes. OPTION M510 suppresses some of these errors to match MASM 5.1 behavior. MASM 5.1 does not check for illegal usage of the instruction prefixes LOCK, REP, REPE, REPZ, REPNE, and REPNZ.
Illegal usage of these prefixes results in error A2068:

```
instruction prefix not allowed
```

For more information on these instruction prefixes, see “Overview of String Instructions” in Chapter 5. See also “Bug Fixes from MASM 5.1,” earlier in this appendix.

**Size of Constant Operands with OPTION M510**

In MASM 5.1, a large constant value that can fit only in the processor’s default word (4 bytes for .386 and .486, 2 bytes otherwise) is assigned a size attribute of the default word size. The value of the constant affects the number of bytes changed by the instruction. For example,

```
; Legal only with OPTION M510
mov [bx], 0100h
```

is legal in **OPTION M510** mode. Since 0100h cannot fit in a byte, the assembler interprets the value as a word.

Without **OPTION M510**, the assembler never assigns a size automatically. You must state it explicitly with the **PTR** operator, as shown in the following example:

```
; Without OPTION M510
mov [bx], WORD PTR 0100h
```

**Code Labels when Defining Data with OPTION M510**

MASM 5.1 allows a code label definition in a data definition statement if that statement does not also define a data label. MASM 6.1 also allows such definitions if **OPTION M510** is enabled; otherwise it is illegal.

```
; Legal only with OPTION M510
MyCodeLabel:    DW      0
```

**SEG Operator with OPTION M510**

In MASM 5.1, the **SEG** operator returns a label’s segment address unless the frame is explicitly specified, in which case it returns the segment address of the frame. A statement such as **SEG DGROUP: var** always returns **DGROUP**, whereas **SEG var** always returns the segment address of **var**. **OPTION M510** forces this same behavior in MASM 6.1.

If you do not use **OPTION M510**, the behavior of the **SEG** operator is determined by the **OPTION OFFSET** directive, as described in “OPTION OFFSET,” later in this appendix.

In MASM 6.1, the value returned by the **SEG** operator applied to a nonexternal variable depends on compatibility mode:
Without **OPTION M510**, **SEG** returns the address of the frame (the segment, group, or the value assumed to the segment register) if one has been explicitly set.

With **OPTION M510**, **SEG** returns the group if one has been specified. In the absence of a defined group, **SEG** returns the segment where the variable is defined.

**Expression Evaluation with OPTION M510**

By default, MASM 6.1 changes the way expressions are evaluated. In MASM 5.1,

\[
\text{var} - 2[\text{bx}]
\]

is parsed as

\[
(\text{var} - 2)[\text{bx}]
\]

Without **OPTION M510**, you must rewrite the statement, since the assembler parses it as

\[
\text{var} - (2[\text{bx}])
\]

which generates an error.

**Length and Size of Labels with OPTION M510**

With **OPTION M510**, you can apply the **LENGTH** and **SIZE** operators to any label. For a code label, **SIZE** returns a value of 0FFFFh for **NEAR** and 0FFFEh for **FAR**. **LENGTH** always returns a value of 1. For strings, **SIZE** and **LENGTH** both return 1.

Without **OPTION M510**, **SIZE** returns values of 0FF01h, 0FF02h, 0FF04h, 0FF05h, and 0FF06h for **SHORT**, **NEAR16**, **NEAR32**, **FAR16**, and **FAR32** labels, respectively. **LENGTH** returns 1 except when used with **DUP**, in which case it returns the outermost count. For arrays initialized with **DUP**, **SIZE** returns the length multiplied by the size of the type.

The **LENGTHOF** and **SIZEOF** operators in MASM 6.1 handle arrays much more consistently. These operators return the number of data items and the number of bytes in an initializer. For a description of **SIZEOF** and **LENGTHOF**, see the following sections in Chapter 5: “Declaring and Referencing Arrays,” “Declaring and Initializing Strings,” “Defining Structure and Union Variables,” and “Defining Record Variables.”

**Comparing Types Using EQ and NE with OPTION M510**

With **OPTION M510**, the assembler converts types to a constant value before comparisons with **EQ** and **NE**. Code types are converted to values of 0FFFFh
(near) or 0FFFEh (far). If **OPTION M510** is not enabled, the assembler converts types to constants only when comparing them with constants. Thus, MASM 6.1 recognizes only equivalent qualified types as equal expressions.

For existing MASM 5.1 code, these distinctions affect only the use of the **TYPE** operator in conjunction with **EQ** and **NE**. The following example illustrates how the assembler compares types with and without compatibility mode:

```assembly
MYSTRUCT      STRUC
  f1          DB      0
  f2          DB      0
MYSTRUCT      ENDS

; With OPTION M510
val     =       (TYPE MYSTRUCT) EQ WORD    ; True: 2 EQ 2
val     =       2 EQ WORD                  ; True:  2 EQ 2
val     =       WORD EQ WORD               ; True:  2 EQ 2
val     =       SWORD EQ WORD              ; True:  2 EQ 2

; Without OPTION M510
val     =       (TYPE MYSTRUCT) EQ WORD    ; False: MyStruct NE WORD
val     =       2 EQ WORD                  ; True:  2 EQ 2
val     =       WORD EQ WORD               ; True:  WORD EQ WORD
val     =       SWORD EQ WORD              ; False: SWORD NE WORD
```

**Use of Constant and PTR as a Type with OPTION M510**

You can use a constant as the left operand to **PTR** in compatibility mode. Otherwise, you must use a type expression. With **OPTION M510**, a constant must have a value of 1 (**BYTE**), 2 (**WORD**), 4 (**DWORD**), 6 (**FWORD**), 8 (**QWORD**) or 10 (**TBYTE**). The assembler treats the constant as the
parenthesized type. Note that the \texttt{TYPE} operator yields a type expression, but the \texttt{SIZE} operator yields a constant.

; With \texttt{OPTION M510}

\begin{verbatim}
MyData  DW      0

    mov     WORD PTR [bx], 10           ; Legal
    mov     (TYPE MyData) PTR [bx], 10  ; Legal
    mov     (SIZE MyData) PTR [bx], 10  ; Legal
    mov     2 PTR [bx], 10              ; Legal
\end{verbatim}

; Without \texttt{OPTION M510}

\begin{verbatim}
MyData  WORD    0

    mov     WORD PTR [bx], 10           ; Legal
    mov     (TYPE MyData) PTR [bx], 10  ; Legal

;       mov     (SIZE MyData) PTR [bx], 10  ; Illegal
;       mov     2 PTR [bx], 10              ; Illegal
\end{verbatim}

\subsection*{Structure Type Cast on Expressions with \texttt{OPTION M510}}

In compatibility mode, use the \texttt{PTR} operator to type-cast a constant to a structure type. This is most often done in data initializers to affect the CodeView information of the data label. Without \texttt{OPTION M510}, the assembler generates an error.

\begin{verbatim}
MYSTRC  STRUC
    f1    DB      0
MYSTRC  ENDS

MyPtr   DW      MYSTRC PTR 0    ; Illegal without \texttt{OPTION M510}
\end{verbatim}

In MASM 6.1, the initializer type does not influence CodeView’s type information.

\subsection*{Hidden Coercion of OFFSET Expression Size with \texttt{OPTION M510}}

When programming for the 80386 or 80486, the size of an \texttt{OFFSET} expression can be 2 bytes for a symbol in a \texttt{USE16} segment, or 4 bytes for a symbol in a \texttt{USE32} or \texttt{FLAT} segment. With \texttt{OPTION M510}, you can use a 32-bit \texttt{OFFSET} expression in a 16-bit context. Without \texttt{OPTION M510}, you must use the \texttt{LOWWORD} operator to convert the offset size.
.386

; With OPTION M510

seg32 SEGMENT USE32
MyLabel WORD 0
seg32 ENDS

seg16 SEGMENT USE16 'code' ; With OPTION M510:
    mov ax, OFFSET MyLabel ; Legal
    mov ax, LOWWORD OFFSET MyLabel ; Legal
    mov eax, OFFSET MyLabel ; Legal
seg16 ENDS

; Without OPTION M510

seg32 SEGMENT USE32
MyLabel WORD 0
seg32 ENDS

seg16 SEGMENT USE16 'code' ; Without OPTION M510:
    mov ax, OFFSET MyLabel ; Illegal
    mov ax, LOWWORD offset MyLabel ; Legal
    mov eax, OFFSET MyLabel ; Legal
seg16 ENDS

Specifying Radixes with OPTION M510

If the current radix in your code is greater than 10 decimal, MASM 6.1 allows the radix specifiers B (binary) and D (decimal) only in compatibility mode. You must change B to Y for binary, and D to T for decimal, since both B and D are legitimate hexadecimal values, making numbers such as 12D ambiguous. If you want to keep B and D as radix specifiers when the current radix is greater than 10, you must specify OPTION M510. For more information about radices, see “Integer Constants and Constant Expressions” in Chapter 1.

Naming Conventions with OPTION M510

By default, MASM 5.1 does not write the names of public variables in uppercase to the object file, even when a language type of PASCAL, FORTRAN, or BASIC is specified.

Unless you use OPTION M510, these language types in MASM 6.1 write identifier names in uppercase, even with the /Cp or /Cx command-line options. When you link with /NOI, case must match in the object files to resolve externals.
**Length Significance of Symbol Names with OPTION M510**

With MASM 5.1, only the first 31 characters of a symbol name are considered significant, and only the first 31 characters of a public or external symbol name are placed in the object file.

Without **OPTION M510**, the entire name is considered significant. The maximum number of characters placed in the object file is controlled with the `/H` number command-line option, with a default of 247 (the maximum length of an identifier in MASM 6.1).

**String Defaults in Structure Variables with OPTION M510**

In compatibility mode, a constant initializer can override a structure field initialized with a string value. Without **OPTION M510**, only another string or a list can override a string initializer. To update your code, surround the constant override value with angle brackets or curly braces to indicate a list with one element.

```assembly
MTSTRUCT        STRUCT
MyString        BYTE        "This is a string"
MTSTRUCT        ENDS

; With OPTION M510
MyInst          MTSTRUCT    <0>

; Without OPTION M510, either of these statements is correct
MyInst          MTSTRUCT    <<0>>
MyInst          MTSTRUCT    {<0>}
```

**Effects of the `?` Initializer in Data Definitions with OPTION M510**

As described in “Declaring and Initializing Strings” in Chapter 5, the assembler treats the `?` initializer as either zero or as an unspecified value. In compatibility mode, however, the assembler always treats the `?` initializer as zero unless it is used with the **DUP** operator. In this case, the assembler allocates space, but does not initialize it with any value.

**Current Address Operator with OPTION M510**

In compatibility mode, the current address operator (`$`) applied to a structure returns the offset of the first byte of the structure. When **OPTION M510** is not enabled, `$` returns the offset of the current field in the structure.

**Segment Association for FAR Externals with OPTION M510**

In MASM 5.1, you must place an **EXTRN** directive for a variable in the same segment that holds the variable. For far data, this often entails opening and closing a segment just to place the **EXTRN** statement.
MASM 6.1 offers much greater flexibility in where `EXTERN` and `EXTERNDEF` statements can appear, as described in “Positioning External Declarations” in Chapter 8. However, in compatibility mode, MASM 6.1 emulates the behavior of MASM 5.1.

**Defining Aliases Using EQU with OPTION M510**

In MASM 5.1, you can equate one symbol with another. These equates are called “aliases.”

Unless you specify **OPTION M510**, MASM 6.1 does not allow aliases defined with `EQU`. An immediate expression or text must appear as the right operand of an `EQU` directive. Change aliases to use the `TEXTEQU` directive, described in “Text Macros” in Chapter 9. This change may cause an expression to evaluate differently.

The following examples illustrate the differences between MASM 5.1 code, MASM 6.1 code with **OPTION M510**, and MASM 6.1 code without **OPTION M510**:

```asm
; MASM 5.1 code
var1    EQU     3
var2    EQU     var1    ; var2 taken as an alias
          ; var2 references var1 anywhere var2 is
          ; used as a symbol

; MASM 6.1 with OPTION M510
var1    EQU     3
var2    EQU     var1    ; var2 taken as a var2 EQU <var1>
          ; var2 substituted for var1 whenever
          ; text macros substituted

; MASM 6.1 without OPTION M510
var1    EQU     3
var2    EQU     var1    ; Treated as var2 EQU 3
```
Difference in Text Macro Expansions with OPTION M510

MASM 6.1 recursively expands text macros used as values, whereas MASM 5.1 simply replaces the text macro with its value. The following example illustrates the difference:

; With OPTION M510

tm1 EQU <contains tm2>
tm2 EQU <value>
tm3 CATSTR tm1 ; == <contains tm2>

; Without OPTION M510

tm3 CATSTR tm1 ; == <contains value>

Conditional Directives and Missing Operands with OPTION M510

MASM 5.1 considers a missing argument to be a zero. MASM 6.1 requires an argument unless OPTION M510 is enabled.

OPTION OLDSTRUCTS

This section describes changes in MASM 6.1 that apply to structures. With OPTION OLDSTRUCTS or OPTION M510:

- You can use plus operator (+) in structure field references.
- Labels and structure field names cannot have the same name with OPTION OLDSTRUCTS.

Plus Operator Not Allowed with Structures

By default, each reference to structure member names must use the dot operator (.) to separate the structure variable name from the field name. You cannot use the dot operator as the plus operator (+) or vice versa.

To convert your code so that it does not need OPTION OLDSTRUCTS:

- Qualify all structure field references.
- Change all uses of the dot operator (.) that occur outside of structure references to use the plus operator (+).
If you remove `OPTION OLDSTRUCTS` from your code, the assembler generates errors for all lines requiring change. Using the dot operator in any context other than for a structure field results in error A2166:

```
structure field expected
```

Unqualified structure references result in error A2006:

```
undefined symbol : identifier
```

The following example illustrates how to change MASM 5.1 code from the old structure references to the new type in MASM 6.1:

```masm
; OPTION OLDSTRUCTS (simulates MASM 5.1)
structname       STRUC
    a BYTE  ?
    b WORD  ?
structname       ENDS

structinstance  structname <>
    mov  ax, [bx].b              ; This code assembles
    mov  al, structinstance.a   ; correctly only with
    mov  ax, [bx].4              ; OPTION OLDSTRUCTS
                      ; or OPTION M510

; OPTION NOOLDSTRUCTS (the MASM 6.1 default)
structname       STRUCT
    a BYTE  ?
    b WORD  ?
structname       ENDS

structinstance  structname <>
    mov  ax, [bx].structname.b  ; Add qualifying type
    mov  al, structinstance.a   ; No change needed
    mov  ax, [bx]+4              ; Change dot to plus

; Alternative methods in MASM 6.1
; Either this:
    ASSUME  bx:PTR structname
    mov    ax, [bx]
; or this:
    mov    ax, (structname PTR[bx]).b
```
Duplicate Structure Field Names
With the default, \texttt{OPTION NOOLDSTRUCTS}, label and structure field names may have the same name. With \texttt{OPTION OLDSTRUCTS} (the MASM 5.1 default), labels and structure fields cannot have the same name. For more information, see “Structures and Unions” in Chapter 5.

\textbf{OPTION OLDMACROS}
This section describes how MASM 5.1 and 6.1 differ in their handling of macros. Without \texttt{OPTION OLDMACROS} or \texttt{OPTION M510}, MASM 6.1 changes the behavior of macros in several ways. If you want the MASM 5.1 macro behavior, add \texttt{OPTION OLDMACROS} or \texttt{OPTION M510} to your MASM 5.1 code.

Separating Macro Arguments with Commas
MASM 5.1 allows white spaces or commas to separate arguments to macros. MASM 6.1 with \texttt{OPTION NOOLDMACROS} (the default) requires commas between arguments. For example, in the macro call

\begin{verbatim}
MyMacro var1 var2 var3, var4
\end{verbatim}

\texttt{OPTION OLDMACROS} causes the assembler to treat all four items as separate arguments. With \texttt{OPTION NOOLDMACROS}, the assembler treats

\begin{verbatim}
var1 var2 var3
\end{verbatim}

as one argument, since the items are not separated with commas. To convert your macro code, replace spaces between macro arguments with a single comma.

New Behavior with Ampersands in Macros
The default \texttt{OPTION NOOLDMACROS} causes the assembler to interpret ampersands (\&) within a macro differently than does MASM 5.1. MASM 5.1 requires one ampersand for each level of macro nesting. \texttt{OPTION OLDMACROS} emulates this behavior.

Without \texttt{OPTION OLDMACROS}, MASM 6.1 removes ampersands only once no matter how deeply nested the macro. To update your MASM 5.1 macros, follow this simple rule: replace every sequence of ampersands with a single ampersand. The only exception is when macro parameters immediately precede and follow the ampersand, and both require substitution. In this case, use two ampersands. For a description of the new rules, see “Substitution Operator” in Chapter 9.
This example shows how to update a MASM 5.1 macro:

```masm
; OPTION OLDMACROS (emulates MASM 5.1 behavior)
createNames macro arg
    irp    tail, <Next, Last>
    irp    num <1, 2>
    ; Define more names of the form abcNext1?
    arg&&tail&&&num&&&?   label   BYTE
ENDM
ENDM

; OPTION NOOLDMACROS (the MASM 6.1 default)
createNames macro arg
    for    tail, <Next, Last>  ; FOR is the MASM 6.1 synonym for irp
    for    num <1, 2>        ; synonym for irp
    ; Define more names of the form abcNext1?
    arg&&tail&&num&?   label   BYTE
ENDM
ENDM
```

**OPTION DOTNAME**

MASM 5.1 allows names of identifiers to begin with a period. The MASM 6.1 default is **OPTION NODOTNAME**. Adding **OPTION DOTNAME** to your code enables the MASM 5.1 behavior.

If you don’t want to use this directive in your source code, rename the identifiers whose names begin with a period.

**OPTION EXPR16**

MASM 5.1 treats expressions as 16-bit words if you do not specify `.386` or `.386P` directives. MASM 6.1 by default treats expressions as 32-bit words, regardless of the CPU type. You can force MASM 6.1 to use the smaller expression size with the **OPTION EXPR16** statement.

Unless your MASM 5.1 code specifies `.386` or `.386P`, **OPTION M510** also sets 16-bit expression size. You can selectively disable this by following **OPTION M510** with the **OPTION EXP32** directive, which sets the size back to 32 bits. You cannot have both **OPTION EXP32** and **OPTION EXPR16** in your program.

It may not be easy to determine the effect of changing from 16-bit internal expression size to 32-bit size. In most cases, the 32-bit word size does not affect the MASM 5.1 code. However, problems may arise because of differences in
intermediate values during evaluation of expressions. You can compare the files for differences by generating listing files with the /Fl and /Sa command-line options with and without **OPTION EXPR16**.

**OPTION OFFSET**

The information in this section is relevant only if your MASM 5.1 code does not use the **.MODEL** directive. With no **.MODEL**, MASM 5.1 computes offsets from the start of the segment, whereas MASM 6.1 computes offsets from the start of the group. (With **.MODEL**, MASM 5.1 also computes offsets from the start of the group.)

To force MASM 6.1 to emulate 5.1 behavior, specify either **OFFSET:SEGMENT** or **OPTION M510**. Both directives cause the assembler to compute offsets relative to the segment if you do not include **.MODEL**.

To selectively enable MASM 6.1 behavior, place the directive **OPTION OFFSET:GROUP** after **OPTION M510**. In this case, you should ensure each **OFFSET** statement has a segment override where appropriate. The following example shows how **OPTION OFFSET:SEGMENT** affects code written for MASM 5.1:

```assembly
OPTION OFFSET:SEGMENT
MyGroup GROUP MySeg
MySeg SEGMENT 'data'
MyLabel LABEL BYTE
DW OFFSET MyLabel ; Relative to MySeg
DW OFFSET MyGroup:MyLabel ; Relative to MyGroup
DW OFFSET MySeg:MyLabel ; Relative to MySeg
MySeg ENDS
```

In the preceding example, the first **OFFSET** statement computes the offset of **MyLabel** relative to **MySeg**. Without **OFFSET:SEGMENT**, MASM 6.1 returns the offset relative to **MyGroup**. To maintain the correct behavior with **OFFSET:GROUP**, specify a segment override, as shown in the following. The other two **OFFSET** statements already include overrides, and so do not require modification.

```assembly
OPTION OFFSET:GROUP
MyGroup GROUP MySeg
MySeg SEGMENT 'data'
MyLabel LABEL BYTE
DW OFFSET MySeg:MyLabel ; Relative to MySeg
DW OFFSET MyGroup:MyLabel ; Relative to MyGroup
DW OFFSET MySeg:MyLabel ; Relative to MySeg
MySeg ENDS
```
When not in compatibility mode, the **OPTION OFFSET** directive determines whether the **SEG** operator returns a value relative to the group or segment. With **OPTION M510**, **SEG** is always segment-relative by default, regardless of the current value of **OPTION OFFSET**.

**OPTION NOSCOPED**

The information in this section applies only if the **.MODEL** directive in your MASM 5.1 code does not specify a language type. Without a language type, MASM 5.1 assumes code labels in procedures have no “scope”—that is, the labels are not local to the procedure. When not in compatibility mode, MASM 6.1 always gives scope to code labels, even without a language type.

To force MASM 5.1 behavior, specify either **OPTION M510** or **OPTION NOSCOPED** in your code. To selectively enable MASM 6.1 behavior, place the directive **OPTION SCOPED** after **OPTION M510**.

To determine which labels require change, assemble the module without the **OPTION NOSCOPED** directive. For each reference to a label that is not local, the assembler generates error A2006:

```
undefined symbol : identifier
```

**OPTION PROC**

The information in this section applies only if the **.MODEL** directive in your MASM 5.1 code does not specify a language type. Without a language type, MASM 5.1 makes procedures private to the module. By default, MASM 6.1 makes procedures public. You can explicitly change the default visibility to private with either **OPTION M510**, **OPTION PROC:PRIVATE**, or **OPTION PROC:EXPORT**.

To selectively enable MASM 6.1 behavior, place the directive **OPTION PROC:PUBLC** after **OPTION M510**. You can override the default by adding the **PUBLIC** or **PRIVATE** keyword to selected procedures. The following example shows how to change MASM 5.1 code to keep a procedure private:

```asm
; MASM 5.1 (OPTION PROC:PRIVATE)
MyProc PROC NEAR

; MASM 6.1 (OPTION PROC:PUBLC)
MyProc PROC NEAR PRIVATE
```

This is necessary only to avoid naming conflicts between public names in multiple modules or libraries. The symbol table in a listing file shows the visibility (public, private, or export) of each procedure.
OPTION NOKEYWORD

MASM 6.1 has several new keywords that MASM 5.1 does not recognize as reserved. To resolve any conflicts, you can:

- Rename any offending symbols in your code.
- Selectively disable keywords with the OPTION NOKEYWORD directive.

The second option lets you retain the offending symbol names in your code by forcing MASM 6.1 to not recognize them as keywords. For example,

```masm
OPTION NOKEYWORD: <INVOKESTRUC>
```

removes the keywords `INVOKES` and `STRUCT` from the assembler’s list of reserved words. However, you cannot then use the keywords in their intended function, since the assembler no longer recognizes them.

The following list shows MASM 6.1 reserved words new since MASM 5.1:

```
.BREAK .UNTILCXZ .FRSTORD
.CONTINUE .WHILE .FRSTORD
.DOSSEG ADDR FSAVED
.ELSE ALIAS FSAVEV
.ELSEIF BSWAP FSTENV
.ENDIF CARRY? FSTENV
.ENDW CMPXCHG GOTO
.EXIT ECHO HIGHWORD
.IF EXTERN INVD
.ISTALL EXTERNDEF INVLPG
.ISTIF FAR16 INVOKE
.ISTMACRO FAR32 IRETF
.ISTMACROALL FLAT IRETF
.NO87 FLDENVD LENGTHOF
.NOCREF FLDENVW LOOPD
.NOLIST FNSAVED LOOPE
.NOLISTIF FNSAVEW LOOPEW
.NOLISTMACRO FNSTENVD LOOPNE
.REPEAT FNSTENV LOOPNEW
.STARTUP FOR LOOPNZ
.UNTIL FORC LOOPNZW
```
By default, MASM 6.1 does not recognize pass-dependent constructs. Both the `OPTION M510` and `OPTION SETIF2` statements force MASM 6.1 to handle MASM 5.1 constructs that activate on the second assembly pass, such as `.ERR2`, `.IF2`, and `.ELSEIF2`.

Invoke the option like this:

```
OPTION SETIF2: {TRUE | FALSE}
```

When set to TRUE, `OPTION SETIF2` forces all second-pass constructs to activate on every assembly pass. When set to FALSE, second-pass constructs do not activate on any pass. `OPTION M510` implies `OPTION SETIF2:TRUE`.

### Changes to Instruction Encodings

MASM 6.1 contains changes to the encodings for several instructions. In some cases, the changes help optimize code size.

### Coprocessor Instructions

For the 8087 coprocessor, MASM 5.1 adds an extra `NOP` before the no-wait versions of coprocessor instructions. MASM 6.1 does not. In the rare case that the missing `NOP` affects timing, insert `NOP`.

For the 80287 coprocessor or better, MASM 5.1 inserts \texttt{FWAIT} before certain instructions. MASM 6.1 does not prefix any 80287, 80387, or 80486 coprocessor instruction with \texttt{FWAIT}, except for wait forms of instructions that have a no-wait form.

**RET Instruction**

MASM 5.1 generates a 3-byte encoding for \texttt{RET}, \texttt{RETN}, or \texttt{RETF} instructions with an operand value of zero, unless the operand is an external absolute. In this case, MASM 5.1 ignores the parameter and generates a 1-byte encoding.

MASM 6.1 does the opposite. It ignores a zero operand for the return instructions and generates a 1-byte encoding, unless the operand is an external absolute. In this case, MASM 6.1 generates a 3-byte encoding.

Thus, you can suppress epilogue code in a procedure but still specify the default size for \texttt{RET} by coding the return as

\begin{verbatim}
  ret    0
\end{verbatim}

**Arithmetic Instructions**

Versions 5.1 and 6.1 differ in the way they encode the arithmetic instructions \texttt{ADC}, \texttt{ADD}, \texttt{AND}, \texttt{CMP}, \texttt{OR}, \texttt{SUB}, \texttt{SBB}, and \texttt{XOR}, under the following conditions:

- The first operand is either AX or EAX.
- The second operand is a constant value between 0 and 127.

For the AX register, there is no size or speed difference between the two encodings. For the EAX register, the encoding in MASM 6.1 is 2 bytes smaller. The \texttt{OPTION NOSIGNEXTEND} directive forces the MASM 5.1 behavior for \texttt{AND}, \texttt{OR}, and \texttt{XOR}. 
APPENDIX B

BNF Grammar

This appendix provides a complete description of symbols, operators, and directives for MASM 6.1. It uses the Backus-Naur Form (BNF) for grammar notation. You can use BNF grammar to determine the exact syntax for any language component and find all available options for any MASM command.

BNF definitions consist of “nonterminals” and “terminals.” Nonterminals are placeholders within a BNF definition, defined elsewhere in the BNF grammar. Terminals are endpoints in a BNF definition, consisting of MASM 6.1 keywords. In this Appendix, all nonterminals appear in italics type and all terminals appear in bold type.

BNF Conventions

The conventions use different font attributes for different items in the BNF. The symbols and formats are as follows:

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>nonterminal</td>
<td>Italic type indicates nonterminals.</td>
</tr>
<tr>
<td>RESERVED</td>
<td>Terminals in boldface type are literal reserved words and symbols that must be entered as shown. Characters in this context are always case insensitive.</td>
</tr>
<tr>
<td>[]</td>
<td>Objects enclosed in double brackets ([ ] ) are optional. The brackets do not actually appear in the source code.</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>.8086</td>
<td>Underlined items indicate the default option if one is given.</td>
</tr>
<tr>
<td>default typeface</td>
<td>Characters in the set described or listed can be used as terminals in MASM statements.</td>
</tr>
</tbody>
</table>
How to Use the BNF Grammar

To illustrate the use of the BNF, Figure B.1 diagrams the definition of the `TYPEDEF` directive, starting with the nonterminal `typedefDir`.

The entries under each horizontal brace in Figure B.1 are terminals (such as `NEAR16`, `NEAR32`, `FAR16`, and `FAR32`) or nonterminals (such as `qualifier`, `qualifiedType`, `distance`, and `protoSpec`) that can be further defined. Each italicized nonterminal in the `typedefDir` definition is also an entry in the BNF.

Three vertical dots indicate a branching definition for a nonterminal that, for the sake of simplicity, this figure does not illustrate.

The BNF grammar allows recursive definitions. For example, the grammar uses `qualifiedType` as a possible definition for `qualifiedType`, which is also a component of the definition for `qualifier`.

```

A listing file shows precisely how the assembler translates your source file into machine code. The listing documents the assembler’s assumptions, memory allocations, and optimizations.

MASM creates an assembly listing of your source file whenever you do one of the following:

- Select the appropriate option in PWB.
- Use one of the related source code directives.
- Specify the /Fl option on the MASM command line.

The assembly listing contains both the statements in the source file and the binary code (if any) generated for each statement. The listing also shows the names and values of all labels, variables, and symbols in your file.

The assembler creates tables for macros, structures, unions, records, segments, groups, and other symbols, and places the tables at the end of the assembly listing. Only the types of symbols encountered in the program are included. For example, if your program has no macros, the symbol table does not have a macros section.

Generating Listing Files

To generate a listing file from within PWB, follow these steps:

1. From the Options menu, choose MASM Options.
2. In the MASM Options dialog box, choose Set Debug or Release Options.

The dialog box for Set Debug or Release Options lists the choices summarized in Table C.1. This table also shows the equivalent source code directives and command-line options.
### Table C.1 Options for Generating or Modifying Listing Files

</tbody>
</table>

¹ Select MASM Options from the Options menu, then choose Set Dialog Options from the MASM Options dialog box.
2 See “Conditional Directives” in Chapter 1

Precedence of Command-Line Options and Listing Directives

Since command-line options and source code directives can specify opposite behavior for the same listing file option, the assembler interprets the commands according to the following precedence levels. Selecting PWB options is equivalent to specifying /Fl /Sx on the command line:

- /Sa overrides any source code directives that suppress listing.
- Source code directives override all command-line options except /Sa.
- .NOLIST overrides other listing directives such as .NOLISTIF and .LISTMACROALL.
- The /Sx, /Ss, /Sp, and /Sl options set initial values for their respective features. Directives in the source file can override these command-line options.

Reading the Listing File

The first half of the listing shows macros from the include file DOS.MAC, structure declarations, and data. After the .DATA directive, the columns on the left show offsets and initialized byte values within the data segment.

Instructions begin after the .CODE directive. The three columns on the left show offsets, instruction timings, and binary code generated by the assembler. The columns on the right list the source statements exactly as they appear in the source file or as expanded by a macro. Various symbols and abbreviations in the middle column provide information about the code, as explained in the following section. The subsequent section, “Symbols and Abbreviations,” explains the meanings of listing symbols.

Generated Code

The assembler lists the code generated from the statements of a source file. With the /Sc command-line switch, which generates instruction timings, each line has this syntax:

```
offset [timing] [code]
```

The `offset` is the offset from the beginning of the current code segment. The `timing` shows the number of cycles the processor needs to execute the instruction. The value of `timing` reflects the CPU type; for example, specifying the .386 directive produces instruction timings for the 80386 processor. If the statement generates code or data, `code` shows the numeric value in hexadecimal.
notation if the value is known at assembly time. If the value is calculated at run
time, the assembler indicates what action is necessary to compute the value.

When assembling under the default .8086 directive, timing includes an effective
address value if the instruction accesses memory. The 80186/486 processors do
not use effective address values. For more information on effective address
timing, see the “Processor” section in the Reference book.

Error Messages

If any errors occur during assembly, each error message and error number
appears directly below the statement where the error occurred. An example of
an error line and message is:

\texttt{mov \ ax, [\ dx][\ di]}
\texttt{listst.asm(77): error A2031: must be index or base register}

Symbols and Abbreviations

The assembler uses the symbols and abbreviations shown in Table C.2 to
indicate addresses that need to be resolved by the linker or values that were
generated in a special way. The example in this section illustrates many of these
symbols.

The example listing was produced using “List Generated Instructions” and “List
Instruction Timings” in PWB. These options correspond to the ML command-
line switches /Fl /Sg /Sc.

Table C.2 Symbols and Abbreviations in Listings

<table>
<thead>
<tr>

Reading Tables in a Listing File

The tables at the end of a listing file list the macros, structures, unions, records, segments, groups, and symbols that appear in a source file. These tables are not printed in the previous sample listing, but are summarized as follows.

**Macro Table**
Lists all macros in the main file or the include files. Differentiates between macro functions and macro procedures.

**Structures and Unions Table**
Provides the size in bytes of the structure or union and the offset of each field. The type of each field is also given.

**Record Table**
“Width” gives the number of bits of the entire record. “Shift” provides the offset in bits from the low-order bit of the record to the low-order bit of the field. “Width” for fields gives the number of bits in the field. “Mask” gives the maximum value of the field, expressed in hexadecimal notation. “Initial” gives the initial value supplied for the field.

**Type Table**
The “Size” column in this table gives the size of the `TYPEDEF` type in bytes, and the “Attr” column gives the base type for the `TYPEDEF` definition.

**Segment and Group Table**
“Size” specifies whether the segment is 16 bit or 32 bit. “Length” gives the size of the segment in bytes. “Align” gives the segment alignment (`WORD`, `PARA`, and so on). “Combine” gives the combine type (`PUBLIC`, `STACK`, and so on). “Class” gives the segment’s class (`CODE`, `DATA`, `STACK`, or `CONST`).

**Procedures, Parameters, and Locals**
Gives the types and offsets from BP of all parameters and locals defined in each procedure, as well as the size and memory location of each procedure.

**Symbol Table**
All symbols (except names for macros, structures, unions, records, and segments) are listed in a symbol table at the end of the listing. The “Name”
column lists the names in alphabetical order. The “Type” column lists each symbol’s type.

The length of a multiple-element variable, such as an array or string, is the length of a single element, not the length of the entire variable.

If the symbol represents an absolute value defined with an **EQU** or equal sign (=) directive, the “Value” column shows the symbol’s value. The value may be another symbol, a string, or a constant numeric value (in hexadecimal), depending on the type. If the symbol represents a variable or label, the “Value” column shows the symbol’s hexadecimal offset from the beginning of the segment in which it is defined.

The “Attr” column shows the attributes of the symbol. The attributes include the name of the segment (if any) in which the symbol is defined, the scope of the symbol, and the code length. A symbol’s scope is given only if the symbol is defined using the **EXTERN** and **PUBLIC** directives. The scope can be external, global, or communal. The “Attr” column is blank if the symbol has no attribute.
APPENDIX D

MASM Reserved Words

This appendix lists the reserved words recognized by MASM. They are divided primarily by their use in the language. The primary categories are:

- Operands and symbols
- Registers
- Operators and directives
- Processor instructions
- Coprocessor instructions

Reserved words in MASM 6.1 are reserved under all CPU modes. Words enabled in .8086 mode, the default, can be used in all higher CPU modes. To use words from subcategories such as “Special Operands for the 80386” (later in this appendix) requires .386 mode or higher.

You can disable the recognition of any reserved word specified in this appendix by setting the NOKEYWORD option for the OPTION directive. Once disabled, the word can be used in any way as a user-defined symbol (provided the word is a valid identifier). If you want to remove the STR instruction, the MASK operator, and the NAME directive, for instance, from the set of words MASM recognizes as reserved, add this statement to your program:

```
OPTION NOKEYWORD: <STR MASK NAME>
```

Words in this appendix identified with an asterisk (*) are new since MASM 5.1.

Operands and Symbols

The words on the two lists in this section are the operands to certain directives. They have special meaning to the assembler. The words on the first list are not reserved words. They can be used in every way as normal identifiers, without affecting their use as operands to directives. The assembler interprets their use from context.
Even though the words on the first list are not reserved, they should not be defined to be text macros or text macro functions. If they are, they will not be recognized in their special contexts. The assembler does not give a warning if such a redefinition occurs.

APPENDIX E

Default Segment Names

If you use simplified segment directives by themselves, you do not need to know the names assigned for each segment. However, it is possible to mix full segment definitions with simplified segment directives, in which case you need to know the segment names.

Table E.1 shows the default segment names created by each directive.

If you use .MODEL, a _TEXT segment is always defined, even if all .CODE directives specify a name. The default segment name used as part of far-code segment names is the filename of the module. The default name associated with the .CODE directive can be overridden, as can the default names for .FARDATA and .FARDATA?.

The segment and group table at the end of listings always shows the actual segment names. However, the GROUP and ASSUME statements generated by the .MODEL directive are not shown in listing files. For a program that uses all possible segments, group statements equivalent to the following would be generated:

\begin{verbatim}
DGROUP  GROUP    _DATA, CONST, _BSS, STACK
\end{verbatim}

For the tiny model, these ASSUME statements would be generated:

\begin{verbatim}
ASSUME cs: DGROUP, ds: DGROUP, ss: DGROUP
\end{verbatim}

For small and compact models with NEARSTACK, these ASSUME statements would be generated:

\begin{verbatim}
ASSUME cs: _TEXT, ds: DGROUP, ss: DGROUP
\end{verbatim}
For medium, large, and huge models with `NEARSTACK`, these `ASSUME` statements would be generated:

```
ASSUME   cs: name_TEXT, ds: DGROUP, ss: DGROUP
```

* unless the stack type is FARSTACK
Glossary

8087, 80287, or 80387 coprocessor  Intel chips that perform high-speed floating-point and binary coded decimal number processing. Also called math coprocessors. Floating-point instructions are supported directly by the 80486 processor.

A
address  The memory location of a data item or procedure. The expression can represent just the offset (in which case the default segment is assumed), or it can be in segment:offset format.

address constant  In an assembly-language instruction, an immediate operand derived by applying the SEG or OFFSET operator to an identifier.

address range  A range of memory bounded by two addresses.

addressing modes  The various ways a memory address or device I/O address can be generated. See “far address,” “near address.”

aggregate types  Data types containing more than one element, such as arrays, structures, and unions.

animate  A debugging feature in which each line in a running program is highlighted as it executes. The Animate command from the CodeView debugger Run menu turns on animation.

API (application programming interface)  A set of system-level routines that can be used in an application program for tasks such as basic input/output and file management. In a graphics-oriented operating environment like Microsoft Windows, high-level support for video graphics output is part of the Windows graphical API.

arg  In PWB, a function modifier that introduces an argument or an editing function. The argument may be of any type and is passed to the next function as input. For example, the PWB command Arg text arg Copy passes the text argument text arg to the function Copy.

argument  A value passed to a procedure or function. See “parameter.”

array  An ordered set of continuous elements of the same type.

ASCII (American Standard Code for Information Interchange)  A widely used coding scheme where 1-byte numeric values represent letters, numbers, symbols, and special characters. There are 256 possible codes. The first 128 codes are standardized; the remaining 128 are special characters defined by the computer manufacturer.

assembler  A program that converts a text file containing mnemonically coded microprocessor instructions into the corresponding binary machine code. MASM is an assembler. See “compiler.”

assembly language  A programming language in which each line of source code corresponds to a specific microprocessor instruction. Assembly language gives the programmer full access to the computer’s hardware and produces the most compact, fastest executing code. See “high-level language.”

assembly mode  The mode in which the CodeView debugger displays the assembly-language equivalent of the high-level code being executed. CodeView obtains the assembly-
language code by disassembling the executable file. See “source mode.”

**B**

**base address** The starting address of a stack frame. Base addresses are usually stored in the BP register.

**base name** The portion of the filename that precedes the extension. For example, SAMPLE is the base name of the file SAMPLE.ASM.

**BCD (binary coded decimal)** A way of representing decimal digits where 4 bits of 1 byte are a decimal digit, coded as the equivalent binary number.

**binary** Referring to the base-2 counting system, whose digits are 0 and 1.

**binary expression** A Boolean expression consisting of two operands joined by a binary operator and resolving to a binary number.

**binary file** A file that contains numbers in binary form (as opposed to ASCII characters representing the same numbers). For example, a program file is a binary file.

**binary operator** A Boolean operator that takes two arguments. The **AND** and **OR** operators in assembly language are examples of binary operators.

**BIOS (Basic Input/Output System)** The software in a computer’s ROM which forms a hardware-independent interface between the CPU and its peripherals (for example, keyboard, disk drives, video display, I/O ports).

**bit** Short for binary digit. The basic unit of binary counting. Logically equivalent to decimal digits, except that bits can have a value of 0 or 1, whereas decimal digits can range from 0 through 9.

**breakpoint** A user-defined condition that pauses program execution while debugging. CodeView can set breakpoints at a specific line of code, for a specific value of a variable, or for a combination of these two conditions.

**buffer** A reserved section of memory that holds data temporarily, most often during input/output operations.

**byte** The smallest unit of measure for computer memory and data storage. One byte consists of 8 bits and can store one 8-bit character (a letter, number, punctuation mark, or other symbol). It can represent unsigned values from 0 to 255 or signed values between –128 and +127.

**C**

**C calling convention** The convention that follows the C standard for calling a procedure—that is, pushing arguments onto the stack from right to left (in reverse order from the way they appear in the argument list). The C calling convention permits a variable number of arguments to be passed.

**chaining (to an interrupt)** Installing an interrupt handler that shares control of an interrupt with other handlers. Control passes from one handler to the next until a handler breaks the chain by terminating through an **IRET** instruction. See “interrupt handler,” “hooking (an interrupt).”

**character string** See “string.”

**clipboard** In PWB, a section of memory that holds text deleted with the Copy, Ldelete, or Sdelete functions. Any text attached to the clipboard deletes text already there. The Paste function inserts text from the clipboard at the current cursor position.

**.COM** The filename extension for executable files that have a single segment containing both code and data. Tiny model produces .COM files.
**combine type**  The segment-declaration specifier (AT, COMMON, MEMORY, PUBLIC, or STACK) which tells the linker to combine all segments of the same type. Segments without a combine type are private and are placed in separate physical segments.

**compact**  A memory model with multiple data segments but only one code segment.

**compiler**  A program that translates source code into machine language. Usually applied only to high-level languages such as Basic, FORTRAN, or C. See “assembler.”

**constant**  A value that does not change during program execution. A variable, on the other hand, is a value that can—and usually does—change. See “symbolic constant.”

**constant expression**  Any expression that evaluates to a constant. It may include integer constants, character constants, floating-point constants, or other constant expressions.

**D**

**debugger**  A utility program that allows the programmer to execute a program one line at a time and view the contents of registers and memory in order to help locate the source of bugs or other problems. Examples are CodeView and Symdeb.

**declaration**  A construct that associates the name and the attributes of a variable, function, or type. See “variable declaration.”

**default**  A setting or value that is assumed unless specified otherwise.

**definition**  A construct that initializes and allocates storage for a variable, or that specifies either code labels or the name, formal parameters, body, and return type of a procedure. See “type definition.”

**description file**  A text file used as input for the NMAKE utility.
device driver  A program that transforms I/O requests into the operations necessary to make a specific piece of hardware fulfill that request.

Dialog Command window  The window at the bottom of the CodeView screen where dialog commands can be entered, and previously entered dialog commands can be reviewed.

direct memory operand  In an assembly-language instruction, a memory operand that refers to the contents of an explicitly specified memory location.

directive  An instruction that controls the assembler’s state.

displacement  In an assembly-language instruction, a constant value added to an effective address. This value often specifies the starting address of a variable, such as an array or multidimensional table.

DLL  See “dynamic-link library.”

double-click  To rapidly press and release a mouse button twice while pointing the mouse cursor at an object on the screen.

double precision  A real (floating-point) value that occupies 8 bytes of memory (MASM type REAL8). Double-precision values are accurate to 15 or 16 digits.

doubleword  A 4-byte word (MASM type DWORD).

drag  To move the mouse while pointing at an object and holding down one of the mouse buttons.

dump  To display or print the contents of memory in a specified memory range.

dynamic linking  The resolution of external references at load time or run time (rather than link time). Dynamic linking allows the called subroutines to be packaged, distributed, and maintained independently of their callers. Windows extends the dynamic-link mechanism to serve as the primary method by which all system and nonsystem services are obtained. See “linking.”

dynamic-link library (DLL)  A library file that contains the executable code for a group of dynamically linked routines.

dynamic-link routine  A routine in a dynamic-link library that can be linked at load time or run time.

E

element  A single member variable of an array of like variables.

environment block  The section of memory containing the MS-DOS environment variables.

errorlevel code  See “exit code.”

.EXE  The filename extension for a program that can be loaded and executed by the computer. The small, compact, medium, large, huge, and flat models generate .EXE files. See “.COM,” “tiny.”

exit code  A code returned by a program to the operating system. This usually indicates whether the program ran successfully.

expanded memory  Increased memory available after adding an EMS (Expanded Memory Specification) board to an 8086 or 80286 machine. Expanded memory can be simulated in software. The EMS board can increase memory from 1 megabyte to 8 megabytes by swapping segments of high-end memory into lower memory. Applications must be written to the EMS standard in order to make use of expanded memory. See “extended memory.”

expression  Any valid combination of
mathematical or logical variables, constants, strings, and operators that yields a single value.

**extended memory** Physical memory above 1 megabyte that can be addressed by 80286–80486 machines in protected mode. Adding a memory card adds extended memory. On 80386-based machines, extended memory can be made to simulate expanded memory by using a memory-management program.

**extension** The part of a filename (of up to three characters) that follows the period (.). An extension is not required but is usually added to differentiate similar files. For example, the source-code file MYPROG.ASM is assembled into the object file MYPROG.OBJ, which is linked to produce the executable file MYPROG.EXE.

**external variable** A variable declared in one module and referenced in another module.

**F**

**far address** A memory location specified with a segment value plus an offset from the start of that segment. Far addresses require 4 bytes—two for the segment and two for the offset. See “near address.”

**field** One of the components of a structure, union, or record variable.

**fixup** The linking process that supplies addresses for procedure calls and variable references.

**flags register** A register containing information about the status of the CPU and the results of the last arithmetic operation performed by the CPU.

**flat** A nonsegmented linear address space. Selectors in flat model can address the entire 4 gigabytes of addressable memory space. See “segment,” “selector.”

**formal parameters** The variables that receive values passed to a function when the function is called.
**forward declaration** A function declaration that establishes the attributes of a symbol so that it can be referenced before it is defined, or called from a different source file.

**frame** The segment, group, or segment register that specifies the segment portion of an address.

**G**

**General-Protection (GP) fault** An error that occurs in protected mode when a program accesses invalid memory locations or accesses valid locations in an invalid way (such as writing into ROM areas).

**gigabyte** 1,024 megabytes, or 1,073,741,824 bytes.

**global** See “visibility.”

**global constant** A constant available throughout a module. Symbolic constants defined in the module-level code are global constants.

**global data segment** A data segment that is shared among all instances of a dynamic-link routine; in other words, a single segment that is accessible to all processes that call a particular dynamic-link routine.

**global variable** A variable that is available (visible) across multiple modules.

**granularity** The degree to which library procedures can be linked as individual blocks of code. In Microsoft libraries, granularity is at the object-file level. If a single object file containing three procedures is added to a library, all three procedures will be linked with the main program even if only one of them is actually called.

**group** A collection of individually defined segments that have the same segment base address.

**H**

**handle** An arbitrary value that an operating system supplies to a program (or vice versa) so that the program can access system resources, files, peripherals, and so forth, in a controlled fashion.

**handler** See “interrupt handler.”

**hexadecimal** The base-16 numbering system whose digits are 0 through F (the letters A through F represent the decimal numbers 10 through 15). This is often used in computer programming because it is easily converted to and from the binary (base-2) numbering system the computer itself uses.

**high-level language** A programming language that expresses operations as mathematical or logical relationships, which the language’s compiler then converts into machine code. This contrasts with assembly language, in which the program is written directly as a sequence of explicit microprocessor instructions. Basic, C, COBOL, and FORTRAN are examples of high-level languages. See “assembly language,” “compiler.”

**hooking (an interrupt)** Replacing an address in the interrupt vector table with the address of another interrupt handler. See “interrupt handler,” “interrupt vector table,” “unhooking (an interrupt).”

**huge** A memory model (similar to large model) with more than one code segment and more than one data segment. However, individual data items can be larger than 64K, spanning more than one segment. See “large.”

**identifier** A name that identifies a register or memory location.
**IEEE format** A standard created by the Institute of Electrical and Electronics Engineers for representing floating-point numbers, performing math with them, and handling underflow/overflow conditions. The 8087 family of coprocessors and the emulator package implement this format.

**immediate expression** An expression that evaluates to a number that can be either a component of an address or the entire address.

**immediate operand** In an assembly-language instruction, a constant operand that is specified at assembly time and stored in the program file as part of the instruction opcode.

**import library** A pseudo library that contains addresses rather than executable code. The linker reads the addresses from an import library to resolve references to external dynamic-link library routines.

**include file** A text file with the .INC extension whose contents are inserted into the source-code file and immediately assembled.

**indirect memory operand** In an assembly-language instruction, a memory operand whose value is treated as an address that points to the location of the desired data. See “pointer.”

**instruction** The unit of binary information that a CPU decodes and executes. In assembly language, instruction refers to the mnemonic (such as LDS or SHL) that the assembler converts into machine code.

**instruction prefix** See “prefix.”

**interrupt** A signal to the processor to halt its current operation and immediately transfer control to an interrupt handler. Interrupts are triggered either by hardware, as when the keyboard detects a keypress, or by software, as when a program executes the INT instruction. See “interrupt handler.”

**interrupt handler** A routine that receives processor control when a specific interrupt occurs.

**interrupt service routine** See “interrupt handler.”

**interrupt vector** An address that points to an interrupt handler.

**interrupt vector table** A table maintained by the operating system. It contains addresses (vectors) of current interrupt handlers. When an interrupt occurs, the CPU branches to the address in the table that corresponds to the interrupt’s number. See “interrupt handler.”

**K**

**keyword** A word with a special, predefined meaning for the assembler. Keywords cannot be used as identifiers.

**kilobyte (K)** 1,024 bytes.

**L**

**label** A symbol (identifier) representing the address of a code label or data objects.

**language type** The specifier that establishes the naming and calling conventions for a procedure. These are BASIC, C, FORTRAN, PASCAL, STDCALL, and SYSCALL.

**large** A memory model with more than one code segment and more than one data segment, but with no individual data item larger than 64K (a single segment). See “huge.”

**library** A file that contains modules of compiled code. MS-DOS programs use normal run-time libraries, from which the linker extracts modules and combines them with other object modules to create executable program files. Windows-based programs can use dynamic-link libraries (see), which the operating system loads and links to calling programs. See also “import library.”
**linked list**  A data structure in which each entry includes a pointer to the location of the adjoining entries.

**linking**  In normal static linking, the process in which the linker resolves all external references by searching run-time and user libraries, and then computes absolute offset addresses for these references. Static linking results in a single executable file. In dynamic linking (see), the operating system, rather than the linker, provides the addresses after loading the modules into separate parts of memory.

**local constant**  A constant whose scope is limited to a procedure or a module.

**local variable**  A variable whose scope is confined to a particular unit of code, such as module-level code, or a procedure. See “module-level code.”

**logical device**  A symbolic name for a device that can be mapped to a physical (actual) device.

**logical line**  A complete program statement in source code, including the initial line of code and any extension lines.

**logical segment**  A memory area in which a program stores code, data, or stack information. See “physical segment.”

**low-level input and output routines**  Run-time library routines that perform unbuffered, unformatted input/output operations.

**LSB (least-significant bit)**  The bit lowest in memory in a binary number.

**M**

**machine code**  The binary numbers that a microprocessor interprets as program instructions. See “instruction.”

**macro**  A block of text or instructions that has been assigned an identifier. When the assembler sees this identifier in the source code, it substitutes the related text or instructions and assembles them.

**main module**  The module containing the point where program execution begins (the program’s entry point). See “module.”

**math coprocessor**  See “8087, 80287, or 80387 coprocessor.”

**medium**  A memory model with multiple code segments but only one data segment.

**megabyte**  1,024 kilobytes or 1,048,576 bytes.

**member**  One of the elements of a structure or union; also called a field.

**memory address**  A number through which a program can reference a location in memory.

**memory map**  A representation of where in memory the computer expects to find certain types of information.

**memory model**  A convention for specifying the number and types of code and data segments in a module. See “tiny,” “small,” “medium,” “compact,” “large,” “huge,” and “flat.”

**memory operand**  An operand that specifies a memory location.

**meta**  A prefix that modifies the subsequent PWB function.

**mnemonic**  A word, abbreviation, or acronym that replaces something too complex to remember or type easily. For example, **ADC** is the mnemonic for the 8086’s add-with-carry instruction. The assembler converts it into machine (binary) code, so it is not necessary to remember or calculate the binary form.
**module** A discrete group of statements. Every program has at least one module (the main module). In most cases, a module is the same as a source file.

**module-definition file** A text file containing information that the linker uses to create a Windows-based program.

**module-level code** Program statements within any module that are outside procedure definitions.

**MSB (most-significant bit)** The bit farthest to the left in a binary number. It represents \(2^{n-1}\), where \(n\) is the number of bits in the number.

**multitasking operating system** An operating system in which two or more programs, processes, or threads can execute simultaneously.

**N**

**naming convention** The way the compiler or assembler alters the name of a routine before placing it into an object file.

**NAN** Acronym for “not a number.” Math coprocessors generate NANs when the result of an operation cannot be represented in IEEE format. For example, if two numbers being multiplied have a product larger than the maximum value permitted, the coprocessor returns a NAN instead of the product.

**near address** A memory location specified by the offset from the start of the value in a segment register. A near address requires only 2 bytes. See “far address.”

**nonreentrant** See “reentrant procedure.”

**null character** The ASCII character encoded as the value 0.

**null pointer** A pointer to nothing, expressed as the value 0.

**O**

**.OBJ** Default filename extension for an object file.

**object file** A file (normally with the extension .OBJ) produced by assembling source code. It contains relocatable machine code. The linker combines object files with run-time and library code to create an executable file.

**offset** The number of bytes from the beginning of a segment to a particular byte within that segment.

**opcode** The binary number that represents a specific microprocessor instruction.

**operand** A constant or variable value that is manipulated in an expression or instruction.

**operator** One or more symbols that specify how the operand or operands of an expression are manipulated.

**option** A variable that modifies the way a program performs. Options can appear on the command line, or they can be part of an initialization file (such as TOOLS.INI). An option is sometimes called a switch.

**output screen** The CodeView screen that displays program output. Choosing the Output command from the View menu or pressing F4 switches to this screen.

**overflow** An error that occurs when the value assigned to a numeric variable is larger than the allowable limit for that variable’s type.

**overlay** A program component loaded into memory from disk only when needed. This technique reduces the amount of free RAM needed to run the program.
**Parameter** The name given in a procedure definition to a variable that is passed to the procedure. See “argument.”

**Passing by reference** Transferring the address of an argument to a procedure. This allows the procedure to modify the argument’s value.

**Passing by value** Transferring the value (rather than the address) of an argument to a procedure. This prevents the procedure from changing the argument’s original value.

**Physical segment** The true memory address of a segment, referenced through a segment register.

**Pointer** A variable containing the address of another variable. See “indirect memory operand.”

**Precedence** The relative position of an operator in the hierarchy that determines the order in which expression elements are evaluated.

**Preemptive** Having the power to take precedence over another event.

**Prefix** A keyword (LOCK, REP, REPE, REPNE, REPNZ, or REPZ) that modifies the behavior of an instruction. MASM 6.1 ensures the prefix is compatible with the instruction.

**Private** Data items and routines local to the module in which they are defined. They cannot be accessed outside that module. See “public.”

**Privilege level** A hardware-supported feature of the 80286–80486 processors that allows the programmer to specify the exclusivity of a program or process. Programs running at low-numbered privilege levels can access data or resources at higher-numbered privilege levels, but the reverse is not true. This feature reduces the possibility that malfunctioning code will corrupt data or crash the operating system.

**Privileged mode** The term applied to privilege level 0. This privilege level should be used only by a protected-mode operating system. Special privileged instructions are enabled by .286P, .386P, and .486P. Privileged mode should not be confused with protected mode.
procedure call  An expression that invokes a procedure and passes actual arguments (if any) to the procedure.

procedure definition  A definition that specifies a procedure’s name, its formal parameters, the declarations and statements that define what it does, and (optionally) its return type and storage class.

procedure prototype  A procedure declaration that includes a list of the names and types of formal parameters following the procedure name.

process  Generally, any executing program or code unit. This term implies that the program or unit is one of a group of processes executing independently.

Program Segment Prefix (PSP)  A 256-byte data structure at the base of the memory block allocated to a transient program. It contains data and addresses supplied by MS-DOS that a program can read during execution.

protected mode  The 80286–80486 operating mode that permits multiple processes to run and not interfere with each other. This feature should not be confused with privileged mode.

public  Data items and procedures that can be accessed outside the module in which they are defined. See “private.”

qualifiedtype  A user-defined type consisting of an existing MASM type (intrinsic, structure, union, or record), or a previously defined TYPEDEF type, together with its language or distance attributes.

radix  The base of a number system. The default radix for MASM and CodeView is 10.

RAM (random-access memory)  Computer memory that can be both written to and read from. RAM data is volatile; it is usually lost when the computer is turned off. Programs are loaded into and executed from RAM. See “ROM.”

real mode  The normal operating mode of the 8086 family of processors. Addresses correspond to physical (not mapped) memory locations, and there is no mechanism to keep one application from accessing or modifying the code or data of another. See “protected mode.”

record  A MASM variable that consists of a sequence of bit values.

reentrant procedure  A procedure that can be safely interrupted during execution and restarted from its beginning in response to a call from a preemptive process. After servicing the preemptive call, the procedure continues execution at the point at which it was interrupted.

register operand  In an assembly-language instruction, an operand that is stored in the register specified by the instruction.

register window  The optional CodeView window in which the CPU registers and the flag register bits are displayed.

registers  Memory locations in the processor that temporarily store data, addresses, and processor flags.

regular expression  A text expression that specifies a pattern of text to be matched (as opposed to matching specific characters).

relocatable  Not having an absolute address. The assembler does not know where the label, data, or code will be located in memory, so it generates a fixup record. The linker provides the address.

return value  The value returned by a function.

ROM (read-only memory)  Computer memory that can only be read from and cannot be modified. ROM data is permanent; it is not lost when the
machine is turned off. A computer’s ROM often contains BIOS routines and parts of the operating system. See “RAM.”

**routine** A generic term for a procedure or function.

**run-time dynamic linking** The act of establishing a link when a process is running. See “dynamic linking.”

**run-time error** A math or logic error that can be detected only when the program runs. Examples of run-time errors are dividing by a variable whose value is zero or calling a DLL function that doesn’t exist.

**S**

**scope** The range of statements over which a variable or constant can be referenced by name. See “global constant,” “global variable,” “local constant,” “local variable.”

**screen swapping** A screen-exchange method that uses buffers to store the debugging and output screens. When you request the other screen, the two buffers are exchanged. This method is slower than flipping (the other screen-exchange method), but it works with most adapters and most types of programs.

**scroll bars** The bars that appear at the right side and bottom of a window and some list boxes. Dragging the mouse on the scroll bars allows scrolling through the contents of a window or text box.

**segment** A section of memory, limited to 64K with 16-bit segments or 4 gigabytes with 32-bit segments, containing code or data. Also refers to the starting address of that memory area.

**sequential mode** The mode in CodeView in which no windows are available. Input and output scroll down the screen, and the old output scrolls off the top of the screen when the screen is full. You cannot examine previous commands after they scroll off the top. This mode is required with computers that are not IBM compatible.

**selector** A value that indirectly references a segment address. A protected-mode operating system, such as Windows, assigns selector values to programs, which use them as segment addresses. If a program attempts to use an unassigned selector, it triggers a General-Protection fault (see).

**shared memory** A memory segment that can be accessed simultaneously by more than one process.

**shell escape** A method of gaining access to the operating system without leaving CodeView or losing the current debugging context. It is possible to execute MS-DOS commands, then return to the debugger.

**sign extended** The process of widening an integer (for example, going from a byte to a word, or a word to a doubleword) while retaining its correct value and sign.

**signed integer** An integer value that uses the most-significant bit to represent the value’s sign. If the bit is one, the number is negative; if zero, the number is positive. See “two’s complement,” “unsigned integer,” “MSB.”

**single precision** A real (floating-point) value that occupies 4 bytes of memory. Single-precision values are accurate to six or seven decimal places.

**single-tasking environment** An environment in which only one program runs at a time. MS-DOS is a single-tasking environment.

**small** A memory model with only one code segment and only one data segment.

**source file** A text file containing symbols that define the program.

**source mode** The mode in which CodeView
displays the assembly-language source code that represents the machine code currently being executed.

**stack**  An area of memory in which data items are consecutively stored and removed on a last-in, first-out basis. A stack can be used to pass parameters to procedures.

**stack frame**  The portion of a stack containing a particular procedure’s local variables and parameters.

**stack probe**  A short routine called on entry to a function to verify that there is enough room in the program stack to allocate local variables required by the function.

**stack switching**  Changing the stack pointers to point to another stack area.

**stack trace**  A symbolic representation of the functions that are being executed to reach the current instruction address. As a function is executed, the function address and any function arguments are pushed on the stack. Therefore, tracing the stack shows the active functions and their arguments.

**standard error**  The device to which a program can send error messages. The display is normally standard error.

**standard input**  The device from which a program reads its input. The keyboard is normally standard input.

**standard output**  The device to which a program can send its output. The display is normally standard output.

**statement**  A combination of labels, data declarations, directives, or instructions that the assembler can convert into machine code.

**status bar**  See “linking.”
**static linking**  The line at the bottom of the PWB or CodeView screen. The status bar displays text position, keyboard status, current context of execution, and other program information.

**STDCALL**  A calling convention that uses caller stack cleanup if the `VARARG` keyword is specified. Otherwise the called routine must clean up the stack.

**string**  A contiguous sequence of characters identified with a symbolic name.

**string literal**  A string of characters and escape sequences delimited by single quotation marks (‘ ’) or double quotation marks (“ ”).

**structure**  A set of variables that may be of different types, grouped under a single name.

**structure member**  One of the elements of a structure. Also called a field.

**switch**  See “option.”

**symbol**  A name that identifies a memory location (usually for data).

**symbolic constant**  A constant represented by a symbol rather than the constant itself. Symbolic constants are defined with `EQU` statements. They make a program easier to read and modify.

**SYSCALL**  A language type for a procedure. Its conventions are identical to C’s, except no underscore is prefixed to the name.

**tag**  The name assigned to a structure, union, or enumeration type.

**task**  See “process.”

**text**  Ordinary, readable characters, including the uppercase and lowercase letters of the alphabet, the numerals 0 through 9, and punctuation marks.

**text box**  In PWB, a box where you type information needed to carry out a command. A text box appears within a dialog box. The text box may be blank or contain a default entry.

**tiny**  Memory model with a single segment for both code and data. This limits the total program size to 64K. Tiny programs have the filename extension .COM.

**toggle**  A function key or menu selection that turns a feature off if it is on, or on if it is off. Used as a verb, “toggle” means to reverse the status of a feature.

**TOOLS.INI**  A file containing initialization information for many of the Microsoft utilities, including PWB.

**two’s complement**  A form of base-2 notation in which negative numbers are formed by inverting the bit values of the equivalent positive number and adding 1 to the result.

**type**  A description of a set of values and a valid set of operations on items of that type. For example, a variable of type `BYTE` can have any of a set of integer values within the range specified for the type on a particular machine.

**type checking**  An operation in which the assembler verifies that the operands of an operator are valid or that the actual arguments in a function call are of the same types as the function definition’s parameters.

**type definition**  The storage format and attributes for a data unit.

**U**

**unary expression**  An expression consisting of a single operand preceded or followed by a unary operator.

**unary operator**  An operator that acts on a single operand, such as `NOT`. 
underflow  An error condition that occurs when a calculation produces a result too small for the computer to represent.

unhooking (an interrupt)  The act of removing your interrupt handler and restoring the original vector. See “hooking (an interrupt).”

union  A set of values (in fields) of different types that occupy the same storage space.

unresolved external  See “unresolved reference.”

unresolved reference  A reference to a global or external variable or function that cannot be found, either in the modules being linked or in the libraries linked with those modules. An unresolved reference causes a fatal link error.

unsigned integer  An integer in which the most-significant bit serves as part of the number, rather than as an indication of sign. For example, an unsigned byte integer can have a value from 0 to 255. A signed byte integer, which reserves its eighth bit for the sign, can range from -127 to +128. See “signed integer,” “MSB.”

user-defined type  A data type defined by the user. It is usually a structure, union, record, or pointer.

visibility  The characteristic of a variable or function that describes the parts of the program in which it can be accessed. An item has global visibility if it can be referenced in every source file constituting the program. Otherwise, it has local visibility.

W

watch window  The window in CodeView that displays watch statements and their values. A variable or expression is watchable only while execution is occurring in the section of the program (context) in which the item is defined.

window  A discrete area of the screen in PWB or CodeView used to display part of a file or to enter statements.

window commands  Commands that work only in CodeView’s window mode. Window commands consist of function keys, mouse selections, CTRL and ALT key combinations, and selections from pop-up menus.

window mode  The mode in which CodeView displays separate windows, which can change independently. CodeView has mouse support and a wide variety of window commands in window mode.

word  A data unit containing 16 bits (2 bytes). It can store values from 0 to 65,535 (or -32,768 to +32,767).
